CLUSTER 6—ACTINOBACULUM The genus was described on the basis of the distinct phylogenetic position and chemotaxonomic properties of its members (Lawson et al., 1997), which separated them from most representatives of the genus *Actinomyces*. *Actinobaculum* contains the distantly related species *Actinobaculum suis* (basonym *Actinomyces suis*) and *Actinobaculum schaalii* (94.2% 16S rRNA gene sequence similarity). The distinct position of these species, supported by a high bootstrap value of 91%, has also been described in the publications of Pascual Ramos et al. (1997b), Nikolaitchouk et al. (2000) and the more recent species descriptions. The set of signature nucleotides (Table 4) clearly identifies members of this genus.

The Genus *Actinomyces*

The first member of the genus *Actinomyces* was discovered in 1877 when the German veterinarian Otto Bollinger found that lesions of a chronically destructive disease of the jaw and tongue of cattle, previously mistaken for a sarcomatous malignant tumor, contained small particles resembling clusters of crystals (“drusen” or “vugs,” later termed “sulfur granules” in the Angloamerican literature) which chiefly consisted of filamentous, fungus-like structures. The botanist C. O. Harz confirmed the microbial nature of these elements (Harz, 1877) and, because of the radial microscopic configuration of the particles, named the suspected microorganism *Actinomyces* (“ray fungus”) *bovis*, although its culture was not possible until 1890 (Mosselman and Lienaux, 1890). A similar disease in humans was first described by James Israel (Israel, 1878), but attempts to cultivate the pathogen were again fruitless until Bujwid (1889) first succeeded in isolating the organism. A more comprehensive bacteriological description of these pathogens was published by Wolff and Israel (1891), and one of their current designations, *A. israelii*, was introduced by Lachner-Sandoval (1898).

Taxonomy

Breed and Conn (1919) first recommended that *Actinomyces* be considered a *genus conservandum* with *A. bovis* as the type species, and this was accepted by the Winslow Committee in 1920 (Winslow et al., 1920), thereby confirming that *Actinomyce* (*sic*) Meyen 1827, a name proposed for a fungus (*Tremella meteorica*), was not valid.

Originally, the description of the genus was solely based upon the morphology of the filamentous elements produced by *A. bovis* in the granules of bovine infections. The discovery of similar but not identical granules in human infections and the successful cultivation of both *A. bovis* and *A. israelii* added little to this description. Cultural, physiological, and chemical characters only slowly began to influence the definition of the taxon. Pine and Georg (1969) used cellular and colonial morphology, cell wall composition, fermentation end products, and certain physiological characters to define the genus *Actinomyces* in light of more modern approaches to taxonomy. Thus, *Actinomyces propionicus* was removed from the genus and reclassified as *Arachnia propionica* (now: *Propionibacterium propionicum*), as it produced propionic acid as a major fermentation end product and had LL-diaminopimelic acid in its cell wall (Pine and Georg, 1969; Table 2).

Because of persisting taxonomic and nomenclatural uncertainties, as well as the lack of suitable differential characters, it was essentially impossible for many years to separate *A. bovis* reliably from *A. israelii*, and both names were used interchangeably until the reports of Erikson (1940), Thompson (1950), and Pine et al. (1960) finally proved that the causative agents of human and bovine actinomycosis were two taxonomically distinct species. At the same time, the improved taxonomic techniques also allowed the delineation of a first group of additional *Actinomyces* species. Thompson and Lovstedt (1951) proposed the name *A. naeslundii* for a filamentous bacterium which had first been isolated from the human oral cavity by Carl Naeslund in 1925 (Table 1). *Actinomyces viscosus*, which had primarily been described under the genus designation “*Odontomyces*” (Howell et al., 1965), was included in the genus *Actinomyces* after its definition had been changed to accommodate both catalase-positive and catalase-negative bacteria (Georg et al., 1969; Table 3).

However, it soon became apparent that *A. naeslundii* and *A. viscosus* were closely related in terms of physiological characters and antigenic structure (Holmberg and Forsum, 1973a; Fillery et al., 1978; Schofield and Schaal, 1981; Schaal and Gatzert, 1985c). It was even suggested (Gerencser, 1979) that *A. naeslundii* and *A. vis-*

cosus were varieties of a single species. Nevertheless, detailed numerical phenetic analyses (Schaal and Schofield, 1981c; Schaal and Schofield, 1981d; Schofield and Schaal, 1981) revealed that strains labeled *A. naeslundii* and *A. viscosus* formed a set of comparatively stable subclusters, two of which could be equated with typical *A. naeslundii* and *A. viscosus* isolates, respectively. Very similar results were obtained in a recent evaluation of a new phenotypic differentiation system (Taxa Profile®, Merlin, Germany) in which four distinct numerical phenetic clusters could be delineated within the *A. naeslundii* and *A. viscosus* complex (Dahlen, 2004). At least in part, these results have been confirmed using molecular genetic analyses (Coykendall and Munzenmaier, 1979). In particular, the study of Johnson et al. (1990) showed that strains belonging to the *A. naeslundii* and *A. viscosus* complex may be assigned to four genospecies, which were provisionally termed “*A. naeslundii*, genospecies 1,” “*A. naeslundii*, genospecies 2,” “*Actinomyces* serotype WVA 963,” and “*A. viscosus*, serotype I.” *Actinomyces naeslundii*, genospecies 1, contains strains formerly designated “*A. naeslundii*, serotype I.” The *A. naeslundii* genospecies 2 comprises strains of *A. naeslundii* serotype II, *A. naeslundii* serotype III, *A. viscosus* serotype II, and strains that react with both *A. naeslundii* and *A. viscosus* serotype II antisera (so-called “serotype NV strains”). *Actinomyces* serotype WVA 963 had formerly been designated “*A. naeslundii* serotype IV” but was found to be more distantly related to the other organisms of this complex and also occupied a separate position in numerical phenetic studies (Schaal and Schofield, 1981c; Schaal and Schofield, 1981d; Schofield and Schaal, 1981). The hamster isolates of *A. viscosus* (serotype I) appeared to form another separate genospecies.

Gram-positive, predominantly rod-shaped bacteria that had first been isolated from advanced human carious lesions were recognized as a further *Actinomyces* species by Batty (1958) and named “*A. odontolyticus*” (Table 1). The classical *Actinomyces* species mentioned above form two different phylogenetic clusters with *A. bovis*, *A. naeslundii*, *A. viscosus* and *A. israelii* belonging to cluster 1 and *A. odontolyticus* belonging to cluster 2 (Fig. 1).

After further improvement of the chemotaxonomic and physiological tests (and especially after introduction of DNA-DNA pairing and 16S rRNA gene sequencing technologies into the field of actinomycete taxonomy), numerous additional taxa were added to the list of *Actinomyces* species (Table 1). Dent and Williams described three groups of Gram-positive bacteria isolated from the dental plaque of dairy cattle which showed some phenotypic similarity to *A.*

naeslundii or *A. viscosus* but could be differentiated from these species on the basis of cell wall and DNA base composition, DNA-DNA similarity data, polypeptide molecular weight distribution, and a few physiological reactions (Dent and Williams, 1984a; Dent and Williams, 1984b; Dent and Williams, 1984c; Dent and Williams, 1986). The new species designations “*A. denticolens*,” “*A. howellii*” and “*A. slackii*,” respectively, were proposed for these isolates, which all belong to the phylogenetic cluster 1. In contrast, bacteria that were isolated from canine infections and named “*A. hordeovulneris*” by Buchanan et al. (1984b) appear to represent a separate phylogenetic line of descent (cluster 2a; Fig. 1).

Actinomyces meyeri, which was first described by Kurt Meyer (Meyer, 1911) and included in the genus “*Actinobacterium*” by Prévot (1938), was reclassified as *Actinomyces meyeri* by Cato et al. (Cato et al., 1984; Table 3). The genus designation “*Actinobacterium*” lost its standing in nomenclature after the type species of this genus, “*Actinobacterium israelii*,” had been transferred to the genus *Actinomyces* by Breed and Conn (1919), so that “*Actinobacterium meyeri*” remained “a species in search of a genus” for many years. In addition, 16S rDNA sequence data confirm the close affinity of this species to other members of the genus *Actinomyces*, namely in the phylogenetic cluster 2.

The dramatically increasing application of 16S rRNA or rDNA sequencing to Gram-positive rod-shaped bacteria in recent years has led to a host of new or reclassified *Actinomyces* species (Tables 1–3): As far as human isolates are concerned, Stackebrandt and Charfreitag (1990), as well as Johnson et al. (1990), found that strains formerly known as *A. israelii* serovar 2 showed a surprisingly low level of DNA relatedness to *A. israelii* serovar 1 isolates, which led the latter authors to propose the new species *A. gerencseriae* for the serovar 2 strains. In the same study, Johnson et al. (1990) described the species *A. georgiae*, whose members were recovered from gingival crevices of humans with and without periodontitis, but while *A. gerencseriae* belongs to the phylogenetic cluster 1, *A. georgiae* is recovered in cluster 2. Another group of organisms which had primarily been termed CDC group 1 coryneform bacteria and CDC group 1-like coryneform bacteria was assigned to the genus *Actinomyces* as *A. neuui* subsp. *neuui* and *A. neuui* subsp. *anitratus*, respectively, by Funke et al. (1994), although current phylogenetic data indicate that these bacteria, which were chiefly isolated from human abscesses in association with mixed anaerobic flora or blood cultures, represent a separate line of descent (see Phylogeny). *Actinomyces radingae* and *A. turicensis* (Wüst et al., 1995) were both mainly isolated

from human mixed infections (including skin, genital, and urinary tract infections) and belong to the phylogenetic cluster 2.

Actinomyces-like bacteria that had chiefly been recovered from human respiratory tract secretions were termed "*A. graevenitzii*" by Pascual Ramos et al. (1997a). However, several dendrograms derived from 16S rDNA sequences show unequivocally that *A. graevenitzii* strains appear to constitute an isolated phylogenetic lineage within the *Actinomycetaceae*. Similarly, *A. europaeus*, which was described by Funke et al. (1997a) for isolates mainly derived from human abscesses but also from urinary tract infections (Sabbe et al., 1999), is only remotely related to the classical *Actinomyces* species when 16S rDNA sequence similarity is considered (Fig. 1). In contrast, *A. urogenitalis*, which was described by Nikolaitchouk et al. (2000) for human urogenital isolates, represents a member of the phylogenetic core cluster 1 of *Actinomyces* (see Phylogeny), while *A. funkei*, which was proposed by Lawson et al. (2001) for three human strains of different sources including blood cultures, is a member of the phylogenetic core cluster 2.

The most recent members of the genus *Actinomyces* from human sources apparently belong to different phylogenetic clusters. *Actinomyces cardiffensis*, which was described by Hall et al. in 2002, had been isolated from various clinical specimens such as pleural fluid, brain, jaw, pericolic and ear abscesses, as well as intrauterine contraceptive devices, and is also a member of the phylogenetic core cluster 2. In contrast, actinomycetes isolated from infected human dental root canals were described by Collins et al. (2000b) as *A. radidentis* and belong to or are associated with the phylogenetic cluster 1. The single strain described as *A. nasicola* by Hall et al. (2003b) had been recovered from the purulent discharge found in the nasal antrum of an 81-year-old man and shows some 16S rRNA gene sequence relatedness to *A. hordeovulneris*, and to a lesser extent, also to *A. coleocanis* and *A. europaeus*. A second new *Actinomyces* species of human origin, *A. oricola* (Hall et al., 2003d), was isolated from a dental abscess and appears to be phylogenetically related to *A. israelii* and *A. gerencseriae*. The third new member of the genus *Actinomyces* described in 2003 from a human clinical specimen (pus of a patient with pelvic actinomycosis) was termed "*A. hongkongensis*" (Woo et al., 2003) and also showed some 16S rRNA gene relatedness to *A. marimammalium*. The definition of *A. houstonensis* which was proposed by Clarridge and Zhang in 2002 for three human isolates derived from serious subcutaneous abscesses has as yet chiefly been based upon 16S rDNA sequence data and its sufficient phenotypic characterization remains to be per-

formed. This species will therefore not be further considered in this chapter.

Additional new *Actinomyces* species were derived from various animal sources (Table 1): The species designation "*A. hyovaginalis*" was proposed by Collins et al. (1993) for a group of *Actinomyces*-like strains that had been isolated from purulent discharge and aborted fetuses of pigs. These organisms are recovered in the phylogenetic core cluster 2. Fermentative Gram-positive bacteria also derived from pigs and designated "*Actinomyces suis*" pose several taxonomic and nomenclatural problems (Table 2). This species epithet was first used by Gasperini (1892) but had not been validly published and was therefore declared a *nomen dubium* (Slack, 1974). Grässer (1957) isolated bacteria from mastitis of swine, which were again named "*A. suis*." In this case, the name was validly published, but the description was inadequate, and cultures are not available. More recently, Franke (1973) once more described actinomycetes isolated from the udder of swine, which he also called "*A. suis*." The description of Franke's isolates appears to differ from that of Grässer's strains but is strikingly similar to that of *A. hyovaginalis* (Collins et al., 1993), at least as far as physiological characteristics are concerned. Another single bacterial isolate from pig mastitis was found to represent a further new *Actinomyces* species (Hoyles et al., 2001a) in core cluster 2 and was named *A. suimastitidis* (Fig. 1).

Several further new *Actinomyces* species originated from canine and feline lesions. *Actinomyces bowdenii* (Pascual et al., 1999) was isolated from abscesses, pleural fluid, or a pyogranuloma of dogs and a cat, predominantly in mixed culture with additional microbes, and is a member of the phylogenetic cluster 1. *Actinomyces canis* (Hoyles et al., 2000), which was cultured from vaginal secretions or pus of dogs, belongs to cluster 2. A third new canine species, *A. catuli* (Hoyles et al., 2001b), originated from a polymicrobial infection of the lungs and pleural space. The single strain of *A. coleocanis* (Hoyles et al., 2002a) was isolated from the vagina of a cocker spaniel dog. While *A. catuli* is a member of the phylogenetic cluster 1, *A. coleocanis*, together with *A. europaeus*, occupies a separate phylogenetic position.

Actinomyces marimammalium (Hoyles et al., 2001c), which was isolated from seals and a porpoise, was found to branch very deep within the tree of the Actinomycetaceae, so that it also appears to represent a separate line of descent (Fig. 1). The as yet most recent animal *Actinomyces* species, *A. vaccimaxillae* (Hall et al., 2003a), was cultured from pus of a jaw lesion of an adult cow and was described to be phylogenetically related to *A. canis*, *A. hyovag-*

inalis, *A. suimastitidis*, *A. funkei* and *A. turicensis*, respectively.

The species *Actinomyces humiferus* was validly published by Gledhill and Casida in 1969. However, organisms conforming to this description differ considerably from typical members of the genus *Actinomyces* in that they grow at 30°C, have a high DNA G+C content (73 mol%), are sensitive to lysozyme, and occur in high numbers in organically rich soils (Gledhill and Casida, 1969). Also, they were found not to be related phylogenetically to other members of the genus *Actinomyces* and were thus reclassified as *Cellulomonas humilata* (Collins and Pascual, 2000a). Further reclassifications appeared to be appropriate for *Actinomyces bernardiae* (Funke et al., 1995b) and *Actinomyces pyogenes* (Reddy et al., 1982), both of which were transferred to the genus *Arcanobacterium* as *Arcanobacterium bernardiae* and *Arcanobacterium pyogenes*, respectively (Pascual Ramos et al., 1997b; Table 2). *Actinomyces suis* (Ludwig et al., 1992), which had primarily been described as *Eubacterium suis* (Wegienek and Reddy, 1982b) and which is apparently not identical with the swine isolates mentioned as “*A. suis*” above, was reclassified as *Actinobaculum suis* (Lawson et al., 1997; Table 2).

MORPHOLOGICAL CHARACTERISTICS

Cellular Morphology Cells of *Actinomyces* species have been described as being straight or slightly curved rods with or without clubbed ends, variable in shape and size (0.2–1.0 µm in diameter and 1.5–5.0 µm in length), and slender filaments (1 µm in width and 10–50 µm or more in length; Figs. 2 and 3), showing various degrees of true branching and a more or less wavy appearance (Slack, 1974; Slack and Gerencser,

1975; Schaal, 1986a). However, short rods (coccobacillary) or coccoid forms may also be seen and may occur singly, in pairs, or in diphtheroidal arrangements (Y, V, T forms or palisades). All of the *Actinomyces* species are Gram positive, although irregular staining may give rise to a beaded or barred appearance, and they are non-motile and do not form endospores.

After the inclusion of many additional species the cellular morphology of the genus *Actinomyces* covers a wide range of forms so that morphological criteria have largely lost their relevance as taxonomic markers of the genus (Table 5). Thus, these organisms may resemble classical actinomycetes as well as bifidobacteria, corynebacteria, other rod-shaped bacterial species, and even streptococci. Furthermore, the cellular morphology may vary from strain to strain within one species and may be influenced additionally by the composition of the growth medium, its pH, cultural conditions, or the age of cultures.

Filamentous cells are chiefly produced by *A. israelii*, *A. gerencseriae*, *A. hordeovulneris*, and *A. oricola*, although these species may also appear as longer or shorter, possibly diphtheroidal rods with and without branching (Table 5). The majority of species predominantly present themselves as straight or curved rods that may show branching, and some species are primarily characterized by coccobacillary or even coccoid forms (Table 5).

Colony Morphology Microcolonies of filamentous *Actinomyces* species as well as those of *Propionibacterium propionicum* originate from rod-like propagules, usually by apical growth at one or both ends of the rod (Fig. 4), resulting in spider- or cobweb-like structures (Fig. 5) so that it is hardly possible to differentiate these *Actino-*

Data from Dent and Williams (1986c), Schaal (1986b), Johnson et al. (1990), Collins et al. (1993, 2000), Funke et al. (1994, 1997), Wüst et al. (1995), Pascual Ramos et al. (1997), Pascual et al. (1999), Hoyles et al. (2000, 2001a, b, c, 2002), Nikolaitchouk et al. (2000), Lawson et al. (2001), Sarkonen et al. (2001), and Hall et al. (2002).

myces and *Propionibacterium* species on the basis of microcolony morphology. However, after 4–10 h of incubation, the filamentous growth produced by *Propionibacterium propionicum* often appears to be due to apical growth at only one end of the original rod, which places the latter in the periphery of the young microcolony, giving rise to asymmetrical, twig-like structures, whereas the microcolonies of *A. israelii*, *A. gerencseriae* and other *Actinomyces* species predominantly develop with radial symmetry, with the original propagule being located in the center of the “spider” microcolony (Fig. 6). As growth proceeds, a network of interwoven, branching filaments forms whose central parts may gradually undergo various degrees of frag-

mentation so that at the end of this life cycle the centers of the mature colonies may consist predominantly or exclusively of bacillary elements (Fig. 7) that lead to more or less soft and smooth colonies. As degree of primary filament formation (Fig. 8) and rate of fragmentation and cell separation vary considerably both between and within species, any intergrade between highly filamentous colonies with a hard or crumbly texture and a rough appearance and completely bacillary colonies with a soft texture and a smooth surface may be seen.

The filamentous microcolonies of *A. naeslundii* and *A. viscosus* usually grow considerably faster than those of *A. israelii*, and they show early fragmentation of the central parts of the

colony, with comparatively short and slightly thicker radially arranged peripheral hyphae. Furthermore, the filaments of these species develop predominantly on the agar surface, whereas those of *A. israelii* and *A. gerencseriae* tend to grow into the agar below its surface, which reduces their optical refractivity. Although *Actinomyces* species were described as not forming an aerial mycelium, an occasional strain of *A. israelii* or *A. gerencseriae* may produce short aerial hyphae that, because of their higher optical refractivity, are easily distinguished from the substrate filaments (Schaal, 1986a).

Actinomyces colonies mature between 2–5 and 7–17 days of incubation at $36 \pm 1^\circ\text{C}$. Size, texture, and color of the colonies may vary considerably depending on the respective species affiliation as well as on the composition of the growth medium. Strains producing filamentous microcolonies predominantly form rough mature colonies (Table 5) that may retain much of their mycelial appearance, especially in the periphery. Most characteristic among these are the so-

Fig. 9. *Actinomyces israelii*; mature colony ("molar tooth" type), micrograph in obliquely incident light (CC medium, 14 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

called "molar tooth" colonies (Fig. 9), which may be seen in cultures of *A. israelii* and *A. gerencseriae* but also in those of *A. hordeovulneris*. The "bread-crum" colony type is slightly smoother and only occasionally exhibits a filamentous fringe. The latter type may characteristically be found not only in *A. israelii*, *A. gerencseriae*, *A. hordeovulneris* and *A. oricola* cultures but also among rough variants of other taxa such as *A. bovis*, *A. odontolyticus*, *A. naeslundii*, *A. viscosus* and possibly also *A. catuli*. The two rough colony forms, especially the molar-tooth variant, may be very hard and either adhere firmly to the medium or come off *in toto* when an attempt is made to pick them.

Smooth mature colonies may occur in the species mentioned before but are more characteristic of the other *Actinomyces* species. They may be flat or convex with entire, circular or irregular edges and a soft texture. Their surface may be shiny or even mucoid but also granular or matte (Table 5). Usually, the actinomycete colonies are densely opaque although translucent forms (Fig. 10) are not uncommon in species that predominantly or exclusively produce flat smooth colonies (e.g., *A. meyeri* and *A. odontolyticus*).

Most of the *Actinomyces* colonies are white, gray-white, or creamy-white (Table 5). However, pigment production may be observed in a few species, especially when they are grown on blood agar. Thus, *A. cardiffensis* forms creamy to pinkish mature colonies. Those of *A. denticolens* may show a pink coloration. Dark brown growth may be seen in *A. graevenitzii* cultures. *Actinomyces odontolyticus* characteristically grows in brown to deep red colonies in particular after prolonged incubation. *Actinomyces radidentis* and *A. urogenitalis* were reported to produce brownish or reddish colonies, respectively (Table 5).

In liquid media, *Actinomyces* species may grow as discrete cotton pad-like colonies or compact masses of variable size adhering to the

pellicular, or even slimy (predominantly *A. viscosus*) sediments.

CHEMOTAXONOMIC PROPERTIES Many of the 32 species that are currently thought to belong to the genus *Actinomyces* have been described inadequately and their inclusion in the genus was chiefly based upon data derived from 16S rRNA gene sequence analyses. However, comparative analysis of these 16S rRNA gene sequences revealed considerable phylogenetic diversity within the genus *Actinomyces*, with some species forming distinct subgroups while others appear to form individual lines of descent that may also represent the nuclei of additional genera (Pascual Ramos et al., 1997b). Nevertheless, apart from the phylogenetic evidence, little further information is available that could provide additional criteria for the delineation of such new genera. This is especially true for stable taxonomic characters such as chemotaxonomic properties.

Not surprisingly, therefore, the taxonomic affiliation of certain *Actinomyces* species should be considered tentative. Although the species currently classified in the genus apparently dis-

play a broad range of morphological, biochemical and physiological characteristics (Slack, 1974), the set of phenotypic tests used for delineating especially the recently described new taxa often lacks discriminatory power so that it is essentially impossible to distinguish them from each other and from classical species of the genus. Moreover, present members of the genus *Actinomyces* appear to be very heterogeneous chemotaxonomically, in particular with regard to their amino acid composition of the cell-wall peptidoglycan, DNA base ratio values, cell-wall sugars (Table 6), and menaquinone composition, as well as their polar lipid and cellular fatty acid composition.

The mode of cross-linkage and the amino acid composition of the tetrapeptide bridge of the peptidoglycan layer of members of the *Actinomycetaceae* are complex. Following the methods of Schleifer and Kandler (1972), modified by the use of cellulose sheets (Merck, Darmstadt, Germany) for ascending thin-layer chromatography (N. Weiss, unpublished observation), the crosslinking between the amino group of the diamino acid in position 3 of the peptide side chain and the carboxyl group of D-alanine in

position 4 of the adjacent tetrapeptide varies between members of the Actinomycetaceae. The type abbreviated A5 (Schleifer and Seidl, 1985) is *Actinomyces europaeus*, and *Actinobaculum schaalii* and *Arcanobacterium pluranimalium* possess subtype A5 α (L-Lys-L-Lys-D-Glu; Funke et al., 1997; Lawson et al., 1997, 2001). *Actinomyces radingae* also exhibits this subtype with L-lysine in position 3 of the tetrapeptide being partially replaced by L-ornithine (L-Lys[L-Orn]-L-Lys-D-Glu; Wüst et al., 1995). *Actinomyces turicensis* contains peptidoglycan subtype A5 β with L-ornithine as the diamino acid in position 3 of the tetrapeptide subunit (L-Orn-L-Lys-D-Glu), which is identical to that described for *A. israelii* (Schleifer and Seidl, 1985; Wüst et al., 1995). In contrast, *A. bovis* was shown to belong to peptidoglycan type A4, which is characterized by L-lysine in position 3 of the tetrapeptide subunit and a D- β -asparagine residue forming the interpeptide bridge (L-Lys-D-Asp; Schleifer and Kandler, 1972).

Though the majority of species have not yet been analyzed with respect to peptidoglycan composition, the detailed structures do not correlate with the affiliation of members to individual genera as currently defined. For example, members of *Actinomyces* exhibit the types L-Orn-L-Lys-D-Glu (*A. georgiae*, *A. gerencseriae*, *A. hyovaginalis*, and *A. turicensis*), L-Lys(L-Orn)-L-Lys-D-Glu (*A. radingae*), or L-Lys-L-Lys-D-Glu (*A. europaeus* and *A. neuii*). *Actinobaculum suis* is defined by the L-Lys-L-Ala-L-Lys-D-Glu type, while members of *Arcanobacterium* exhibit either the latter type (*A. bernardiae* and *A. pyogenes*) or the L-Lys-L-Lys-D-Glu type (*A. haemolyticum* and *A. phocae*). Thus, the distribution of peptidoglycan types, matching by and large the phylogenetic clustering of members of other actinobacterial genera, cannot be used as a sole marker suitable

for supporting a dissection of the genus *Actinomyces* on phylogenetic grounds.

Apart from *A. bovis*, *A. neuii* and *A. europaeus* (Table 6), all of the other species of the genus *Actinomyces* contain ornithine in the cell-wall peptidoglycan, and the reported base ratios of their DNA are 54–70 mol% G+C (Slack and Gerencser, 1975; Schaal, 1986a). The wall of *A. bovis* contains glucose, mannose, rhamnose and 6-deoxytalose. *Actinomyces israelii* contains only galactose, whereas *A. viscosus* contains galactose, rhamnose and 6-deoxytalose (Table 6 and 7). Fucose is found, in addition to other sugars, in the cell wall of *A. meyeri*, *A. turicensis* and *A. hyovaginalis*.

The principal respiratory quinones among the *Actinomyces* species are menaquinones with eight, nine, ten and eleven isoprene units. *Actinomyces canis*, *A. bovis*, *A. graevenitzii*, *A. hordeovulneris* and *A. nasicola* thus far appear to be the only *Actinomyces* species which contain fully unsaturated menaquinones, whereas the other species possess menaquinones with varying degrees of saturation.

Concerning the distribution of polar lipids among the *Actinomyces* species, there are generally two phospholipid types, namely phospholipid type I (with no diagnostic phospholipid) and phospholipid type III (with phosphatidylcholine as diagnostic phospholipid) *sensu* (Lechevalier et al., 1977; Table 7).

The principal cellular fatty acids in members of the genus are straight-chain saturated, straight-chain monounsaturated, and branched-chain fatty acids of the *iso* and *anteiso* type as well as fatty acids which contain a cyclopropane ring. These are variably distributed among the different species.

Comparative chemotaxonomic studies on members of the genus *Actinomyces* indicate that this genus is worthy of dissection into several

Table 7. Chemotaxonomic characteristics of selected members of the genus *Actinomyces*.

Organisms	Chemotaxonomic characteristics				
	Wall sugars	Acyl type	Phospholipid types	Menaquinones	Fatty acids
<i>Actinomyces bovis</i>	Glucose + mannose + rhamnose + 6-deoxytalose	Acetyl	PIII DPG, PC, PI, PIM	MK-8 + MK-9 ^a + MK-10 + methyl-MK-10	S, U
<i>Actinomyces israelii</i>	Galactose	Acetyl	PIII DPG, PG, PC, PI, PIM	MK-10(H ₄) ^a	S, U
<i>Actinomyces naeslundii</i>	Galactose + mannose + rhamnose + 6-deoxytalose	Acetyl	PIII DPG, PG, PC, PI, PIM	MK-9(H ₄) + MK-10(H ₄) ^a	S, U

Abbreviations: DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PC, phosphatidylcholine; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides; MK-n(H_x) represents a partially hydrogenated menaquinone with x hydrogen atoms on the side chain containing n isoprene units; S, straight-chain saturated; and U, monounsaturated.

^aMajor component.

genera, which are characterized by different chemotaxonomic patterns. Details of three such patterns are shown in Table 7. One such pattern is represented by *A. bovis*, the type species of the genus, the second is found in *A. israelii*, and the third is characteristic of *A. viscosus*.

A detailed description of these three different chemotaxonomic patterns found in members of the genus *Actinomyces* follows.

Chemotaxonomic Pattern of *A. bovis* This pattern consists of glucose, mannose, rhamnose and 6-deoxytalose as diagnostic cell-wall sugars. The respiratory quinones are composed of fully unsaturated menaquinones with eight (MK-8), nine (MK-9), and ten (MK-10) isoprene units, with MK-9 as the major menaquinone. In addition to these menaquinones, *methyl*-MK-10 (which is characterized by two fragments in the mass spectrum—one occurs in the lower mass region at *mz*/239 and the second is a strong fragment in the high mass region at *mz*/866) is also detected. Polar lipids consist of phosphatidylcholine as the characteristic phospholipid, i.e., the organism possesses phospholipid type PIII *sensu* Lechevalier et al. (1977), in addition to diphosphatidylglycerol, phosphatidylinositol and phosphatidylinositol dimannosides. The fatty acid profile comprises straight-chain saturated and monounsaturated fatty acids. The muramic acid residue of the peptidoglycan is N-acetylated.

Chemotaxonomic Pattern of *A. israelii* In this pattern, galactose is the only cell-wall sugar. The respiratory quinones only consist of tetrahydrogenated menaquinones with ten isoprene units [MK-10(H₄)] as the major isoprenologue. Polar lipids comprise phosphatidylcholine as diagnostic phospholipids, i.e., phospholipid type III *sensu* (Lechevalier et al., 1977), in addition to diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol and phosphatidylinositol dimannosides. The fatty acid profile consists of straight-chain saturated and monounsaturated fatty acids. However, the fatty acid profile of *Actinomyces gerencseriae* contains branched-chain fatty acids of the *iso* and *anteiso* type in addition. The muramic acid residue of the peptidoglycan is N-acetylated.

Chemotaxonomic Pattern of *A. viscosus* Diagnostic cell-wall sugars are galactose, mannose, rhamnose and 6-deoxytalose. The respiratory quinones are tetrahydrogenated menaquinones with nine [MK-9(H₄)] and ten [MK-10(H₄)] isoprene units, with MK-10(H₄) as the major isoprenologue. The polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylinositol and phosphatidylinositol dimannosides, i.e., phospholipid type PIII *sensu* (Lechevalier

et al., 1977). The fatty acid profile consists of straight-chain saturated and monounsaturated as well as branched-chain fatty acids of the *iso* and *anteiso* type. The latter fatty acids were not detected in *A. naeslundii*. The muramic acid residue of the peptidoglycan is N-acetylated.

PHYSIOLOGICAL PROPERTIES Members of the genus *Actinomyces* display considerable diversity concerning their physiological characteristics. This is especially true for their optimum gaseous growth conditions in which they vary considerably from species to species and even from strain to strain within one species. Some species, especially many of the recently described ones, show good to moderate growth when incubated in air on the surface of suitable agar media. This applies in particular to *A. viscosus* (Howell, 1963a), *A. denticolens* (Dent and Williams, 1984a), *A. hordeovulneris* (Buchanan et al., 1984b), *A. slackii* (Dent and Williams, 1986), *A. hyovaginalis* (Collins et al., 1993), *A. neuui* (Funke et al., 1994), *A. radingae* and *A. turicensis* (Wüst et al., 1995), *A. europaeus* (Funke et al., 1997a), *A. graevenitzii* (Pascual Ramos et al., 1997a), *A. bowdenii* (Pascual et al., 1999), *A. canis* (Hoyles et al., 2000), *A. urogenitalis* (Nikolaitchouk et al., 2000), *A. radidentis* (Collins et al., 2000b), *A. funkei* (Lawson et al., 2001), *A. marimammalium* (Hoyles et al., 2001c), *A. catuli* (Hoyles et al., 2001b), *A. suimastitidis* (Hoyles et al., 2001a), *A. coleocanis* (Hoyles et al., 2002), *A. nasicola* (Hall et al., 2003b), and many strains of *A. naeslundii* and *A. odontolyticus*. However, aerobic growth is usually greatly enhanced when the incubation atmosphere contains at least 5% carbon dioxide or when HCO₃⁻ is added to the medium. In liquid media, aerobic growth is usually better, provided that a large inoculum is used.

In contrast, most strains of *A. israelii*, *A. gerencseriae*, *A. bovis*, *A. meyeri*, *A. hongkongensis*, *A. oricola* and possibly also *A. georgiae* (Schaal, 1986a; Johnson et al., 1990; Hall et al., 2003d; Woo et al., 2003) prefer anaerobic growth conditions (with added CO₂ or HCO₃⁻), although a marked strain variation in aerotolerance has been observed. Anaerobically without CO₂, most strains will not grow at all or will produce only very scanty growth. The same is true for many aerobically grown *Actinomyces* strains when the gaseous atmosphere does not contain additional CO₂.

Because all of the *Actinomyces* species recognized so far are commensals or pathogens of warm-blooded vertebrates, their optimum growth temperature is 30–37°C (Schaal, 1986a). Detailed studies on the temperature requirements of *Actinomyces* species showed that growth may occur well below or above the 30–

37°C range. Most strains of *A. israelii*, *A. naeslundii*, and *A. viscosus* were found to also produce visible growth in the range of 28–32°C (Thompson and Lovestedt, 1951; Howell, 1963a). The hamster strains of *A. viscosus* (serovar 1) grew well at 23°C when the organisms were incubated in air with added CO₂ or in an atmosphere of CO₂ and N₂ on brain heart infusion agar (BHIA; Howell, 1963). This species and *A. naeslundii* may also grow at 45°C (Holmberg and Nord, 1975a). *Actinomyces meyeri* strains were reported to multiply equally well at 30°C and 37°C and nearly as well at 25°C. No growth was obtained at 45°C (Cato et al., 1984).

The minimal nutritional requirements of *Actinomyces* species are not well understood. However, good growth has only been obtained in or on complex media containing either rich biological substrates such as brain heart infusion, meat extract, yeast extract, or serum or a defined and complex mixture of a large variety of organic and inorganic compounds (Schaal, 1986a). Studies using synthetic media were reported (Howell and Pine, 1956; Christie and Porteus, 1962b; Christie and Porteus, 1962c; Christie and Porteus, 1962a; Keir and Porteus, 1962) but were understandably mostly restricted to a few strains. However, modifications or simplifications of the synthetic medium of Howell and Pine (1956) have been developed (Pine and Watson, 1959b; Georg et al., 1964; Heinrich and Korth, 1967) that were tested with a by far greater number of strains. Attempts to further simplify these media have so far always resulted in insufficient growth rates or loss of cultures during subculturing. Thus, the anabolic capacity of *Actinomyces* species is limited (Slack and Gerencser, 1975). These organisms apparently require organic nitrogen (e.g., peptides and amino acids), a fermentable carbohydrate and possibly also vitamins and other growth factors for optimum growth. For instance, *A. meyeri* was found to have an absolute requirement for vitamin K₁, and its multiplication is greatly stimulated by 0.02% Tween 80 and by a fermentable carbohydrate (Cato et al., 1984). Similarly, growth of *A. hordeovulneris* is considerably enhanced when the medium is supplemented with 10–20% (v/v) fetal bovine serum (Buchanan et al., 1984b). On the other hand, purines and pyrimidines were found to be either stimulatory or inhibitory to growth of certain *Actinomyces* strains (Christie and Porteus, 1962a; Keir and Porteus, 1962).

Fermentable carbohydrates are the preferred sources of carbon and energy and, when utilized, are fermented with production of acids but no gas (Lentze, 1938a; Howell et al., 1959; Slack, 1974; Slack and Gerencser, 1975; Dent and

Williams, 1984a). The spectrum of carbohydrates and similar carbon sources that may be metabolized fermentatively by *Actinomyces* species is broad (Tables 8 and 9) with considerable species differences so that carbohydrate fermentation patterns form the traditional basis for phenotypic differentiation of these actinomycetes and related organisms. Glucose is the only sugar that is universally utilized by nearly all of the species currently included in the genus *Actinomyces* (Tables 8 and 9). Only *A. hongkongensis* appears to represent an exception to this rule (Woo et al., 2003).

Anaerobically with added CO₂ or HCO₃[−], the major acidic end products of the fermentative carbohydrate metabolism of *Actinomyces* species are succinic and lactic acids with smaller amounts of acetic and formic acids (Schaal, 1986a). The amount of succinic acid formed depends on the concentration of CO₂ and HCO₃[−] available in the gaseous environment or medium, respectively. Anaerobically without added CO₂, the fermentation of “*A. israelii*” ATCC 10049, which is now considered to belong to the species *A. gerencseriae*, was found to be homolactic (Buchanan and Pine, 1965). In the presence of CO₂, the fermentation is heterolactic with formate, acetate, lactate and succinate as end products. In air with added CO₂, acetate and carbon dioxide are the main end products. Carbon dioxide when present is utilized (Howell and Pine, 1956).

In a detailed study on the carbohydrate metabolism of *A. viscosus* in continuous culture (Hamilton and Ellwood, 1983) under glucose or nitrogen limitation, it was shown that the molar growth yields were lower under nitrogen limitation than under glucose limitation, indicating that the supply of utilizable nitrogen sources may be as important for the growth of this organism in the oral cavity as the presence of suitable carbohydrates.

Energy is produced by substrate phosphorylation, but the amount of ATP formed depends on the cultural conditions. According to the results of Buchanan and Pine (1965), four mols of ATP were formed per mol of glucose when “*A. israelii*” (= *A. gerencseriae*) was grown in air with added CO₂. Only two mols of ATP were produced anaerobically without CO₂.

A few actinomycete enzymes involved in the dissimilation of exogenous carbohydrates or the energy yielding glycolytic pathways were characterized in some detail: The β -galactosidase of *A. viscosus* has a molecular weight of 4.2×10^5 , a K_m for lactose of about 6 mM and a pH optimum of 6.0–6.5 (Kiel et al., 1977b). Invertase activity has been demonstrated both in *A. naeslundii* (Miller, 1974) and *A. viscosus* (Palenik and Miller, 1975; Kiel et al., 1977b). The characteristics of the *A.*

From Schofield and Schaal (1981), Buchanan et al. (1984), Dent and Williams (1984, 1986), Schaal (1986b), Johnson et al. (1990), Collins et al. (1993), Pascual et al. (1999), Hoyles et al. (2000, 2001a, b, c, 2002b), and Hall et al. (2003b).

viscosus invertase were as follows: molecular weight 8.6×10^4 ; K_m for sucrose ~ 71 mM; pH optimum between 5.8 and 6.3. This enzyme was noncompetitively inhibited by fructose-6-phosphate and fructose-1,6-diphosphate (Kiel and Tanzer, 1977a). Fructose-1,6-diphosphate aldolase and phosphate acetyltransferase activities were demonstrated in cell-free extracts of *A. israelii* (Buchanan and Pine, 1967). A nicotinamide adenine dinucleotide-dependent lactate dehydrogenase of *A. viscosus* (Brown et al., 1975) was found to have a molecular weight of 1×10^5 and a pH optimum of 5.5–6.2 and was under negative control by adenosine 5'-triphosphate and inorganic phosphate. Malate and glutamate dehydrogenases were detected in extracts of *A. viscosus*, *A. naeshlundii*, *A. israelii* and *A. gerencseriae* but differed in their electrophoretic mobilities (Fillery et al., 1978). 6-Phosphogluconate dehydrogenase was only demonstrated in *A. naeshlundii* and *A. viscosus*

but not in *A. israelii* or *A. gerencseriae* (Fillery et al., 1978).

The formation of extracellular or cell-associated polymers such as levan, dextran or glycogen, which enable certain *Actinomyces* species to attach directly to the tooth surface, has been studied in detail for *A. viscosus* (Howell and Jordan, 1967; Warner and Miller, 1978; Hamilton and Ellwood, 1983; Imai and Kuramitsu, 1983; Komiyama et al., 1988). The levan produced by this organism formed a capsule tenaciously adhering to the cells under certain conditions (Warner and Miller, 1978). The enzyme levansucrase, which is responsible for the production of this high-molecular-weight substance, was found to occur both in the growth medium and affixed to the cell wall (Pabst, 1977; Pabst et al., 1979). In addition, *A. viscosus* was also shown to exert levan-hydrolyzing activities (Miller and Somers, 1978a). Similar synthetic and degrading capacities for such polymers were

also observed in *A. naeslundii* (Miller and Somers, 1978a; Komiyama et al., 1988).

Actinomyces species do not show pronounced proteolytic activities (Slack and Gerencser, 1975; Schofield and Schaal, 1981). Similarly, the ability to deaminate or decarboxylate amino acids is uncommon in the genus (Schaal, 1986a). However, various other enzymatic activities, which may be useful for classification and identification purposes, have been demonstrated using the API Zym test kit or fluorogenic substrates (Tables 8 and 9).

True β -hemolysis is also not common in the genus *Actinomyces*, although this property has been reported for certain strains of *A. bovis* and *A. odontolyticus*, depending on the animal source of the red blood cells.

Lack of catalase activity was once thought to be one of the major phenotypic properties differentiating *Actinomyces* species from morphologically or physiologically related organisms. However, phylogenetic data have shown that the genus *Actinomyces* contains both catalase-positive and catalase-negative members. *Actinomyces neuii*, *A. radidentis*, *A. viscosus*, *A. bowdenii*, *A. canis*, some strains of *A. catuli*, *A. hordeovulneris*, *A. howellii* and *A. slackii* are catalase-positive.

Habitat

Members of the genus *Actinomyces* have exclusively been found as commensals or pathogens of humans and other warm-blooded animals but never as free-living saprophytes in the environment.

ACTINOMYCES SPECIES AS COMMENSALS OR PATHOGENS OF HUMANS Although the first descriptions of *Actinomyces bovis* and *A. israelii* seemed to indicate that they were obligate pathogens (Bollinger, 1877; Israel, 1878), it soon became apparent that these and possibly all of the other species of the genus *Actinomyces* were primarily natural inhabitants of the body surfaces of healthy humans and other animals. Bergey (1907) was probably the first to describe filamentous bacteria adhering to the teeth and being involved in the formation of dental plaque. Since then, numerous reports have demonstrated the presence of such microbes in the oral cavity of man, showing that the classical pathogenic species, as well as less virulent or non-pathogenic taxa, form a major component of the oral microflora.

Naeslund (1925) was the first to culture facultatively anaerobic, filamentous organisms from the human mouth that differed clearly from the pathogen *Actinomyces israelii*. Identical strains were isolated by Thompson and Lovestedt

(1951) and validly designated *Actinomyces naeslundii*. The first indications that potentially pathogenic actinomycetes are generally present in the oral cavity of healthy humans were obtained by Lord (1910) who was able to produce actinomycosis-like lesions in guinea pigs that had been inoculated with the contents of carious teeth. Emmons (1938) examined an unselected series of 200 pairs of tonsils from routine tonsillectomies and observed organisms indistinguishable from *Actinomyces bovis* (at that time a synonym of *A. israelii*) in 37% of the tonsil pairs studied. From 11% of the specimens, he was even able to culture such microbes. However, no clinical or pathological signs of invasive actinomycete infection were found in these cases. Since then, many other workers (Slack, 1942; Howell et al., 1959; Howell et al., 1962; Slack et al., 1971; Sutter, 1984), using different techniques of demonstrating and identifying the bacteria, have proved that *A. israelii* is a facultatively pathogenic, primarily commensal, resident member of the oral microflora of man. This also applies to *Actinomyces gerencseriae*, which was formerly known as serovar 2 of *A. israelii* (Johnson et al., 1990; Sarkonen et al., 2000).

Similar results were obtained for several other members of the genus *Actinomyces*: *Actinomyces naeslundii*, *A. viscosus*, *A. odontolyticus*, *A. georgiae* and *A. graevenitzii* (Batty, 1958; Socransky, 1970; Slack et al., 1971; Collins et al., 1973; Hill et al., 1977; Sarkonen et al., 2000) were recovered regularly from the oral cavity of more-or-less healthy adults and even of young children. The principal natural habitat of *A. meyeri* appears to be the human periodontal sulcus (Cato et al., 1984).

In addition to *A. israelii*, also *A. naeslundii* and possibly other *Actinomyces* species have been demonstrated in human tonsils (Blank and Georg, 1968; Grüner, 1969; Hotchi and Schwarz, 1972; Garcia Ramos et al., 1984). Furthermore, *A. viscosus* and other fermentative actinomycetes may occasionally be isolated from the uninfected conjunctiva and cornea (Jones and Robinson, 1977; Schaal and Beaman, 1984b).

The occurrence of *Actinomyces* species as normal inhabitants of the intestinal tract has not been documented as clearly. Indirect evidence for the view that these organisms may form a small but significant component of the intestinal flora can be derived from cases of abdominal actinomycoses that developed endogenously after bowel surgery, appendix perforation, or injuries of the intestine. Similarly, the recovery of *A. israelii* from large proportions of diseased appendices (60.3% of the samples examined) suggests the presence of these bacteria in the lower digestive tract (Minsker and Moskovskaya, 1979).

Direct demonstration of fermentative actinomycetes in feces and in contents of the upper intestinal tract has also been possible, although number and conclusiveness of these studies are still limited. Some authors (Slack and Gerencser, 1975) regarded occasional isolations of *A. israelii* from feces (Sutter and Finegold, 1972) as accidental in the sense of a transient rather than a permanent colonization of the intestine. On the other hand, strong selective measures (Fritsche, 1964) apparently allow the isolation of *A. israelii* at least in low numbers from most stool specimens of healthy individuals (D. Fritsche, unpublished results). In addition, Noack-Loebel and co-workers, when comparing the composition of the fecal flora in two groups of primary school age children reported that the numbers of fermentative actinomycetes were significantly influenced by the individual dietary habits (Noack-Loebel et al., 1983). Children with a lacto-ovo-vegetarian diet showed an increase in the fecal numbers of fermentative actinomycetes along with increased Bifidobacterium and Enterobacteriaceae counts as compared to school children with normal, *ad libitum* diet. Furthermore, studies on the composition of the microflora in the duodenal and jejunal fluids suggest that *Actinomyces* species frequently represent an important component of the cultivable flora in the upper intestinal tract (Bernhardt and Knoke, 1984; Justesen et al., 1984).

Similar uncertainties still exist with regard to the actinomycete colonization of the female genital tract, although this problem has recently attracted much more attention than the intestinal occurrence. Previously, the vagina, the cervical canal, and the *cavum uteri* were not considered natural habitats of fermentative actinomycetes (Hanf and Hanf, 1955). Also, in more recent studies, these organisms often could not be demonstrated in healthy women who did not use intrauterine contraceptive devices (IUDs; Jones et al., 1983). However, some reports indicate that at least *A. israelii* and *Propionibacterium propionicum* may occur in the female genital tract independently of the use of IUDs, although these organisms were usually recovered in smaller numbers when no foreign body was present in the *cavum uteri* or cervical canal, respectively. Under the latter circumstances, the percentage of positive specimens ranged from 3% for *A. israelii* (Persson et al., 1983) and 19% for *Actinomyces* species in general (Grice and Hafiz, 1983) to more than 70% for *A. israelii* alone (Persson and Holmberg, 1984). In women wearing IUDs or vaginal pessaries, demonstration of these organisms is easier either in cervicovaginal secretions or on the IUD and in particular on its thread reaching from the *cavum uteri* to the vagina.

Nevertheless, the isolation or microscopic demonstration rates of actinomycetes in material from the female genital tract varied widely between 0% (Schiffer et al., 1978) to more than 80% (Gupta et al., 1976, 1978; Hager et al., 1979; Pine et al., 1981; Traynor et al., 1981; Duguid et al., 1982; Valicenti et al., 1982; Grice and Hafiz, 1983; Persson et al., 1983; Schaal and Pulverer, 1984c; Jarvis, 1985; Eibach et al., 1989). These differing results indicate that sensitivity and specificity of the detection methods used are not comparable and that there could also exist regional, ethnic, social, or even religious differences. Furthermore, it remains to be determined whether the colonization with fermentative actinomycetes in IUD-wearing women possesses any predictive value of existing or imminent gynecological infections. An additional question is posed by the observation that, as in the oral cavity and under pathological conditions, actinomycetes may also occur in association with amoebae in the female genital tract (Arroyo and Quinn, 1989).

Apart from *A. israelii* and *Propionibacterium propionicum*, additional *Actinomyces* species such as *A. gerencseriae*, *A. naeslundii*, *A. viscosus*, *A. odontolyticus*, *A. meyeri*, and *A. cardifensis* were recovered from specimens of the female genital tract (Mitchell and Crow, 1984; Schaal and Pulverer, 1984c; Eibach et al., 1989; Schaal and Lee, 1992c; Hall et al., 2002). Occasionally, two different *Actinomyces* species may be isolated from a single genital specimen. In particular, associations of *A. israelii* and *A. viscosus* or *A. israelii* and *A. odontolyticus* were observed in low frequencies (0.6% of the specimens examined; K. P. Schaal, unpublished observations).

Essentially nothing is known about the natural habitat of the remaining new members of the genus *Actinomyces*. *Actinomyces europaeus*, *A. funkei*, *A. neuui*, *A. radingae*, *A. turicensis*, *A. radidentis*, *A. urogenitalis*, *A. nasicola*, *A. oricola* and *A. hongkongensis* were up to now isolated only from pathological lesions, so that their natural reservoirs remain to be identified.

Apart from *A. georgiae*, essentially all of the human *Actinomyces* species mentioned in this section have been isolated from pathological lesions although in varying frequencies. These cover a broad spectrum of diseases and impairments, among which actinomycoses are the most characteristic disease entities. Clinical and pathological details of these conditions are given in the section on Pathogenicity.

ACTINOMYCES SPECIES AS COMMENSALS OR PATHOGENS OF ANIMALS The extent to which members of the genus *Actinomyces* form a part of the indigenous microflora of healthy domestic

and wild animals is not known in detail. By analogy to the situation in humans, animal actinomycoses might also develop endogenously and their causative agents might therefore also belong to the normal microflora of animal mucous membranes (Slack and Gerencser, 1975; Schaal, 1986a). However, Dent and Williams (1984b), in their study on the microflora of the dental plaque in dairy cattle, were not able to identify as *A. bovis*, any filamentous or diphtheroidal, Gram-positive isolates from healthy cattle; the normal habitat of this species thus awaits definite clarification.

Other members of the genus *Actinomyces* have been demonstrated in healthy animals: Beighton (1985) studied the microbial colonization of the mouth of neonatal monkeys (*Macaca fascicularis*) and found that *A. naeslundii* and, to a lesser extent, *A. viscosus* are already established in the dental plaque of these animals during breast-feeding period, suggesting that these organisms belong to the basic plaque flora which is altered by the diet as the animals mature. *Actinomyces viscosus* (serovar 1) has been isolated from subgingival plaque of hamsters and from cervical plaque of rats (Howell, 1963a; Howell and Jordan, 1963b; Jordan and Keyes, 1964; Jordan and Keyes, 1965a; Bellack and Jordan, 1972). Similarly, *A. denticolens*, *A. howellii* and *A. slackii* were recovered from the dental plaque of cattle (Dent and Williams, 1984a; Dent and Williams, 1984b; Dent and Williams, 1986), as were *A. viscosus*, *A. hordeovulneris* and *A. denticolens* from the gingival margin of healthy cats (Love et al., 1990). The natural habitat of *A. hyovaginalis* was assumed to be the porcine genital tract (Collins et al., 1993), but the organism was also recovered from a large number of tonsils of piglets before and after weaning (Baele et al., 2001).

All of the other recently described *Actinomyces* species from animals were isolated from various clinical conditions in dogs (*A. canis*, *A. bowdenii*, *A. catuli* and *A. coleocanis*), cats (*A. bowdenii*), pigs (*A. suimastitidis*), seals or a porpoise (*A. marimammalium*), and a cow (*A. vac-cimaxillae*), respectively, but their natural habitat has not been established. Some details on the clinical pictures of the infections caused by these and other animal *Actinomyces* species are given in the section on Pathogenicity. The sources of a few *A. israelii* infections reported in animals (Tyrrell et al., 2002) remain to be clarified.

Detection, Isolation and Cultivation

COLLECTION AND TRANSPORT OF CLINICAL SPECIMENS Materials suitable for diagnosing human and animal infections due to *Actinomyces* species are pus, sinus discharge, bronchial secretions, granulation tissue, and biopsy specimens.

During sampling, precautions must be taken against contamination with the indigenous mucosal flora, which physiologically contains fermentative actinomycetes. Whenever possible, pus or tissue should be obtained by transcutaneous puncture or needle biopsy through the carefully disinfected skin (Schaal, 1998). For the diagnosis of thoracic actinomycoses, bronchial secretions should be obtained by transtracheal aspiration; sputum is by no means appropriate. Transthoracic or transabdominal needle-aspiration biopsies are often the only ways of obtaining satisfactory specimens from pulmonary or abdominal lesions (Pollock et al., 1978; Schaal, 1998).

The transport of specimens to the bacteriological laboratory should be expeditious unless a reducing transport medium such as Stuart's transport medium is used, although *Actinomyces* species are less susceptible to oxidative damage than are certain strict anaerobes of the concomitant microflora. Adequate transport media are commercially available (e.g., Port-A-Cul [Becton-Dickinson] and Portagerm [bioMérieux]) and should be used according to the instructions of the manufacturers.

MACROSCOPIC AND MICROSCOPIC EXAMINATION OF CLINICAL SPECIMENS Pus from actinomycotic abscesses or the purulent discharge from sinus tracts occasionally contains large amounts of sulfur granules which give these exudates the macroscopic appearance of a semolina soup (Lentze, 1969; Schaal, 1984a). More often, however, sulfur granules are not immediately apparent and have to be specifically looked for. For this purpose, the purulent material is spread out in a sterile Petri dish and examined for the presence of comparatively hard, yellowish to brownish to reddish particles of up to 1 mm in diameter. These particles are picked with an inoculating needle or loop and used for further examinations.

As pus specimens may contain particles that resemble sulfur granules in terms of size, color or texture without being a typical sulfur granule (e.g., granules of mycetomas and actinomycetomas, microcolonies of other filamentous microorganisms, and particles of necrotic tissue), the nature of suspected granules has to be confirmed by subsequent microscopic examinations as follows.

Microscopy of Suspected Sulfur Granules (Schaal, 1992c)

Microscopy at Low Magnification

Place the granule in the middle of a glass slide. Add one drop of 1% methylene blue solution, place a coverslip on top, and press down gently. View under a microscope in transmitted light at about 100× magnification.

Fig. 12. Actinomycotic sulfur granule, partially disintegrated—note the spherical segment-like structures representing filamentous *Actinomyces* colonies and the surrounding blue-colored material which chiefly consists of leukocytes; micrograph after immersing in 1% methylene blue solution and gently pressing on the cover slip.

Under these conditions, the cauliflower-like appearance of the sulfur granules is easily demonstrated (Fig. 12). Because of its reducing capacity, the microbial center of the granule remains unstained, whereas the surrounding leukocytes, other tissue reaction material, and peripheral hyphae take up the blue color of the stain. After slightly harder pressing of the coverslip, sulfur granules usually disintegrate into spherical or partially spherical elements, which represent actinomycete colonies formed *in vivo*.

Microscopy at High Magnification

Crush a particle between two slides and stain the smears thus obtained with Gram stain. Observe at high magnification (ca. 1000×) using an oil-immersion objective.

Actinomycotic sulfur granules typically show nests of Gram-positive, branched, unevenly curved and irregularly stained filaments and rods. In contrast to granules derived from actinomycetomas, the Gram stain also shows, together with leukocytes, the presence of a variety of additional Gram-positive and Gram-negative bacteria, which represent the obligate concomitant flora (Schaal, 1984a; Fig. 13).

METHODS FOR OBTAINING CAPNOPHILIC OR ANAEROBIC GROWTH CONDITIONS Essentially all of the *Actinomyces* species are capnophilic, requiring increased CO₂ concentrations for optimal growth. Some species prefer also reduction of oxygen tension. In contrast to isolation of strict anaerobes, however, isolation of fermentative actinomycetes usually does not require very elaborate techniques for obtaining an oxygen-free atmosphere. Strains from several species may even be reduced in growth rate when no oxygen at all is present.

Fig. 13. Gram stain prepared from a smear of a crushed actinomycotic sulfur granule. Note the host of various Gram-positive and Gram-negative bacterial forms in addition to the nests (→) of Gram-positive, interwoven and branching filaments which represent the causative *Actinomyces* species.

Thus, the use of pre-reduced media, the roll-tube method, glove boxes, or similar complicated and expensive equipment often employed for growing strict anaerobes is usually not needed for culturing fermentative actinomycetes. However, such procedures may be suitable for special research purposes that require constant and controlled growth conditions. When these methods and devices are used, the detailed descriptions and instructions given in the VPI Anaerobe Laboratory Manual (Holdeman et al., 1977) should be followed. Nevertheless, essentially all of the fermentative actinomycetes can be successfully isolated and subcultured by much simpler techniques.

Although it may seem old-fashioned, the easiest, least expensive, and most widely applicable technique for obtaining growth conditions with moderately reduced oxygen tension and increased CO₂ concentration is Fortner's method (Fortner, 1928). This method is based upon the observation that certain *Enterobacteriaceae*, in particular *Serratia marcescens*, are able to consume oxygen and to produce carbon dioxide when grown in a Petri dish which has been carefully sealed before incubation to make it airtight. Depending on the degree of anaerobiosis and CO₂ enrichment needed for an individual strain, growth of the organism to be cultivated in coculture with *Serratia* starts with some delay but usually within the first 4–8 h of incubation.

Fortner's Method for Obtaining Semi-anaerobic Growth Conditions (Fortner, 1928)

Use only agar media, preferably transparent ones, in glass Petri dishes. Plastic dishes will inevitably cause problems! Inoculate one-half to two-thirds of the agar surface with the material to be examined or with the strain to be subcultured using a platinum loop. Inoculate the remaining agar surface heavily with *Serratia* using a spatula.

Fig. 14. Fortner's method. Top third of the Petri dish: confluent growth of *Serratia marcescens*; lower two thirds: growth of an *Actinomyces israelii* strain. Note its enhanced growth near *Serratia*.

Place the dish upside down upon a glass sheet of appropriate size.

Fix and seal the dish with plasticine to make the system air-tight (Fig. 14). Incubate at $36 \pm 1^\circ\text{C}$ for up to 14 days and examine for microbial growth and filamentous colonies every two days using either a hand lens or a microscope with a long-distance 10 \times objective in transmitted light.

Leakage in the plasticine seal, which may occur when the plasticine is too brittle or the base plate is damp, can easily be detected because *Serratia marcescens* forms nonpigmented growth under shortage of oxygen but becomes red when the system is not completely air-tight.

According to the authors' experience, essentially all of the organisms treated in this chapter can easily be cultured by this method. Even the more aerophilic species such as *Actinomyces viscosus* or *Actinomyces neuii* will grow, although their mature colonies may remain slightly smaller than when incubated under full oxygen tension with added CO_2 . Additional plates to be incubated under CO_2 -enriched conditions are usually not necessary. Thus, Fortner's technique may be considered a universal means of culturing *Actinomyces* species. This method is particularly useful in the clinical microbiological laboratory where measures should be as simple and inexpensive as possible but still optimally efficient in order not to lose important clinical isolates. In this respect, it is an additional advantage that Fortner plates can be checked individually for bacterial growth without disturbing the semi-anaerobic atmosphere.

An alternative way of obtaining anaerobic and/or CO_2 -enriched growth conditions is the use of anaerobic jars or cabinets. The Torbal anaerobic jar with a gas mixture of 80% N_2 :10% H_2 :10% CO_2 or the GasPak jar with a H_2 - CO_2 or only CO_2 generating envelope has been recommended (Slack and Gerencser, 1975). For the more anaerobic strains, jars without catalysts are usually less satisfactory. The catalase-positive *Actinomyces* species, however, will grow only poorly if at all in an oxygen-free gaseous atmosphere. Therefore, when jars with such gas mixtures are used for primary isolation, additional plates have to be incubated aerobically with added CO_2 (5–10%, v/v). A candle jar will be most satisfactory for this purpose, but a GasPak jar with a CO_2 -generating unit as mentioned above also can be employed. Recently, the Oxyrase OxyPlate anaerobe incubation system (Oxyrase, Inc., Mansfield, Ohio, USA) was evaluated (Wiggs et al., 2000) for its ability to support growth of various clinically significant anaerobes including *Actinomyces* species. While some of the strict anaerobes (29.9% of the total number of strains examined) grew better in the anaerobic chamber, nearly all of the *Actinomyces* strains tested showed good growth with the Oxyrase OxyPlate system. A glove box is not needed for growing fermentative actinomycetes.

If the oxygen requirements of an individual isolate are not known and cannot be predicted, tests for oxygen requirements must be performed in order not to lose the strain during subculturing.

Tests for Oxygen Requirements (Slack and Gerencser, 1975)

Agar Slant Method

Prepare the inoculum in the following way from about 3-day-old cultures, either in broth or on plates: Suspend cells obtained by centrifugation of the broth culture or by scraping off from the agar surface in 0.85% saline, and adjust the suspension to a density matching a MacFarland 3 standard. Inoculate eight suitable agar medium slants in cotton-plugged tubes with the suspension of the test organism using a capillary pipette.

Incubate the slants, in duplicate, under the following conditions: 1) For aerobic conditions, place two slants with the original cotton plugs directly into the incubator. 2) For aerobic conditions with added CO_2 , clip off the cotton plugs of two tubes and push the remaining parts into the tube to just above the slant. Place small pledgets of absorbent cotton on top of the plugs, add 5 drops of 10% Na_2CO_3 and 5 drops of 1M KH_2PO_4 to each tube, and close it immediately with a rubber stopper. 3) For anaerobic conditions with added CO_2 , prepare tubes as under 2. In this case, however, add 5 drops of 10% Na_2CO_3 and 5 drops of pyrogallol solution (100 g of pyrogallol in 150 ml of distilled water) to the absorbent cotton. 4) For anaerobic conditions without CO_2 , add 5 drops of 10% KOH and 5 drops of pyrogallol solution to the properly prepared tubes (see 2). Record results after

3 and 7 days of incubation, usually at $36 \pm 1^\circ\text{C}$. If the growth in two corresponding tubes does not seem equal, the test has to be repeated.

Agar Deep Method

Inoculate melted and cooled agar medium, while still liquid, with a suspension of the test organism using a capillary pipette. Push the tip of the pipette to the bottom of the tube and then slowly withdraw it while expelling a drop of inoculum. Gently mix the agar by rotating the tube and allow it to solidify in an upright position. Read the results after 3 and 7 days of incubation by measuring the distance in millimeters between the surface and the zone of maximum growth.

Anaerobiosis for fluid cultures may be obtained by placing tubes with suitable broth media into jars. However, another classical technique, based upon the oxygen-binding effect of sterilized animal tissue particles, can give equal or even better results, especially on primary isolation from clinical specimens. The three most common media that utilize this principle are the Tarozzi medium, cooked-meat medium, and Rosenow broth. In Tarozzi medium, when one solid piece of liver is used, fermentative actinomycetes grow especially well on the surface of the tissue and often produce macroscopically visible, "snowball"- or "cotton-pad"-like colonies (Fig. 11) that can be selectively aspirated with a capillary pipette for further microscopic and cultural examination.

MEDIA AND PROCEDURES FOR ISOLATION AND CULTIVATION FROM CLINICAL SPECIMENS Clinical microbiology laboratories which are involved in the diagnosis of anaerobic infections need reliable, simple and inexpensive isolation procedures which allow rapid and characteristic growth of all of the pathogens present to establish a definite diagnosis as early as possible. This does not necessarily mean that the growth conditions must be optimal and that maximum growth yields must be obtained.

General-Purpose Culture Media Various high-quality, general-purpose culture media have been recommended for primary isolation and subsequent *Actinomyces* isolates. These include fluid thioglycolate broth (THIO), possibly supplemented with 0.1–0.2% sterile rabbit serum; brain heart infusion broth (BHIB); trypticase soy broth (TSB); brain heart infusion agar (BHIA); trypticase soy agar (TSA); heart infusion agar or Columbia agar base supplemented with 5–6% defibrinated rabbit, sheep or horse blood and possibly also (e.g., for *A. meyeri*) with 0.02% Tween 80 and vitamin K₁ (10 µg/ml); and Schaedler broth or agar (Slack and Gerencser, 1975; Schaal and Pulverer, 1981b). Most of these media are commercially available and therefore

should be prepared and used according to the manufacturers' instructions.

Special Nonselective Culture Media Nevertheless, none of these commercial media is equally satisfactory under all clinical circumstances and for all of the agents to be expected. Especially in THIO and BHIB or on BHIA, which are widely employed in the bacteriological diagnosis of actinomycotic infections, growth of the actinomycetes is sometimes poor or cannot be recognized because of the rapid and abundant multiplication of concomitant bacteria. Therefore, in the German Consulting Laboratory for Pathogenic Actinomycetes, an additional medium (CC medium) has been used, which was developed more than 30 years ago at the Institute of Hygiene of the University of Cologne (Heinrich and Korth, 1967) as a modification of the synthetic medium of Howell and Pine (1956). This medium has proved to be extremely useful since it promotes growth of pathogenic fermentative actinomycetes in a way that characteristic filamentous micro- and macrocolonies are formed (Fig. 15), and it also allows long-term maintenance of actinomycete cultures over several years by only requiring subculture of the organisms every six to ten weeks.

CC Medium for Isolating and Maintaining Fermentative Actinomycetes (Heinrich and Korth, 1967).

Mineral and Trace Element Solution

MgSO ₄ · 7H ₂ O	20.0 g
CaCl ₂ · 2H ₂ O	2.0 g
FeSO ₄ · 7H ₂ O	0.4 g
MnSO ₄ · 2H ₂ O	15.0 mg
Na ₂ MoO ₄ · 2H ₂ O	15.0 mg
ZnSO ₄	4.0 mg
CuSO ₄ · 5H ₂ O	0.4 mg
CoCl ₂ · 4H ₂ O	0.4 mg
Boric acid	20.0 mg
Potassium iodide	10.0 mg

Fig. 15. *Actinomyces israelii*; filamentous, spider- or cobweb-like microcolonies, micrograph in situ (CC medium, 48 h at $36 \pm 1^\circ\text{C}$, and Fortner's method).

Dissolve in 1 liter of distilled water and acidify with 10 ml of 10% HCl.

Vitamin Solution

Thiamine · HCl	20 mg
Pyridoxine · HCl	20 mg
Biotin	1 mg
Folic acid	5 mg
Vitamin B ₁₂	(1 mg/100 ml) 1 ml
<i>p</i> -Aminobenzoic acid	20 mg
<i>myo</i> -Inositol	20 mg
Nicotinamide	10 mg
Nicotinic acid	10 mg
Ca-Pantothenate	20 mg

Dissolve in 100 ml of distilled water.

Amino Acid and Vitamin Solution

Casein hydrolysate	12 g
Yeast extract	12 g
L-Cysteine · HCl	500 mg
L-Asparagine	30 mg
DL-Tryptophan	20 mg
Vitamin solution (see above)	12 ml

Dilute with distilled water up to a total amount of 100 ml. Filter-sterilize.

The Final Medium

Dissolve 4 g of KH₂PO₄ in 250 ml of distilled water and adjust to pH 7.6 with NaOH. Add 10 ml of mineral and trace element solution, 500 mg of potato starch dissolved in 70 ml of boiling distilled water, about 20 g of agar (depending on quality), and distilled water to give a final volume of 900 ml. Sterilize by autoclaving at 121°C for 15 min. After cooling to about 50°C, add the entire amino acid and vitamin solution under aseptic conditions. Adjust the final pH to 7.3. Pour the medium into glass Petri dishes.

For cultural analyses of clinical specimens, three to four different media, including a fluid medium, preferably Tarozi broth, should be inoculated. When Tarozi broth is used, the test tube containing the medium is heated in a boiling water bath for about 10 min immediately before use, then quickly cooled down under running tap water, inoculated, and sealed with about 2 ml of sterilized melted petrolatum or paraffin wax. Use of paraffin oil is not recommended.

Modified Tarozi Broth for the Isolation and Subcultivation of Fermentative Actinomycetes (Schaal, 1986a)

Basal Nutrient Broth	
Meat extract	10 g
Peptone (e.g., peptone P; Oxoid)	12 g
NaCl	3 g
K ₂ HPO ₄	2 g

Dissolve the ingredients in a total of 1 liter of distilled water while heating at 80°C and boil subsequently for 20 min. Adjust the pH to 7.5 with NaOH solution.

Preparation of Liver Pieces

Cut fresh guinea pig or beef liver into pieces measuring approximately 2 × 1 × 1 cm and wash them thoroughly in several changes of fresh saline.

Preparation of the Medium

Place the liver pieces into test tubes (1 piece per tube). Add 8 ml of basal nutrient broth supplemented with 0.1% sodium thioglycolate (w/v) to each tube. Stopper the tubes with a cotton plug and sterilize by autoclaving at 121°C for 15 min. After inoculation, seal the tube by adding about 1 ml of sterilized melted petrolatum (petroleum jelly, Vaseline) or paraffin wax.

When using Fortner's method for agar cultures and Tarozi broth for fluid cultures, the media can be checked daily for growth of typical mycelial colonies without disturbing the semi-anaerobic atmosphere. When anaerobic jars or incubators or glove boxes are employed, a duplicate set of media should be inoculated and examined after 3 and 7–10 days of incubation at 36 ± 1°C. In addition, a third set of media has to be incubated in air with added CO₂ (candle jar or GasPak jar with a CO₂-generating unit).

For detecting typical mycelial microcolonies of the actinomycetes including those of *Propionibacterium propionicum* in early growth stages, it is best to examine surface cultures on transparent media under a microscope at 80–100× magnification (Fig. 15). If a long-distance objective is available, cultures can be examined through the medium without opening Fortner plates (Lentze, 1938a).

Removal of concomitant bacteria to obtain pure cultures of the actinomycetes for further examination (Fig. 16) is occasionally difficult, even when the organisms have been subcultured several times or when dilution techniques have been applied. Subculture media supplemented with suitable antibiotics may help in these cases but may inhibit growth of the actinomycetes as well. Commercial disks produced for antibiotic susceptibility testing can be used alternatively.

Fig. 16. Synergistic actinomycotic flora; (→) single colony of *A. israelii*; (↔) colonies of *Actinobacillus actinomycetem-comitans*; (↖) additional concomitant bacteria; micrograph *in situ* in transmitted light (brain heart infusion agar, 14 days at 36 ± 1°C, and Fortner's method).

These disks are placed upon the agar surface after the strain to be purified has been inoculated. Depending on the contaminating organisms, disks that contain metronidazole, colistin or nalidixic acid in usual concentrations can be employed. From their inhibition zones, actinomycete colonies can often be picked easily and transferred to another nonselective plate.

ISOLATION FROM THE ORAL CAVITY OR OTHER NATURAL HABITATS IN HUMANS AND ANIMALS Ecological studies on the prevalence of fermentative actinomycetes in various secretions and concretions of mucous membranes usually require the qualitative demonstration of the various species, their differential quantification, and the determination of their numerical relationships to other members of the respective microflora. Therefore, any losses of viable cells or uncontrolled multiplication must be avoided during sampling and transportation of the specimens. Furthermore, since samples from typical habitats of fermentative actinomycetes (especially gingival crevice, sulcus fluid, plaque material, feces, or cervicovaginal secretions) harbor very high numbers of many different additional indigenous microorganisms, selective culture media are necessary to facilitate the detection and enumeration of specific organisms.

Collection and Transport of Specimens from Natural Habitats For ecological studies or for bacteriological analyses in periodontitis or caries, plaque material, dental calculus, and sulcus fluid represent suitable materials for isolating or demonstrating actinomycetes by molecular methods. When quantitative results are to be obtained, the sampling technique must allow measurements of the original amount of material collected.

Different types of transport media have been applied to oral microbes, including the Stuart medium, a general-purpose transport medium widely used in medical microbiology (Loesche et al., 1972; Syed and Loesche, 1972). The reduced transport fluid (RTF) of Syed and Loesche (Syed and Loesche, 1972) was specifically designed for specimens from the oral cavity.

Reduced Transport Fluid (RTF; Syed and Loesche, 1972)

Stock Mineral Salt Solution No. 1	
K ₂ HPO ₄	0.6%
Stock Mineral Salt Solution No. 2	
NaCl	1.2%
(NH ₄) ₂ SO ₄	1.2%
KH ₂ PO ₄	0.6%
MgSO ₄	0.25%

Final Transport Medium

Stock solution no. 1	75 ml
Stock solution no. 2	75 ml
Ethylenediaminetetraacetate (0.1 M)	10 ml
Na ₂ CO ₃ (8%, w/v)	5 ml
Dithiothreitol (1%; freshly prepared)	20 ml
Resazurin (0.1%; optional)	1 ml
Distilled water	814 ml

Sterilize by membrane filtration (pore size, 0.22 µm). Dispense into 16 × 125-mm screw-cap tubes (dilution tubes) and 18 × 150-mm test tubes (sample-collection tubes).

The pH should be 8 ± 0.2 without adjustment and decrease to 7 in 48 h in the anaerobic glove box atmosphere (85% N₂, 10% H₂, and 5% CO₂).

Microscopic Examination of Specimens from Natural Habitats Gram-stained smears from materials such as dental plaque, cervicovaginal secretions or the microbial growth on IUDs and their threads often contain large amounts of Gram-positive, branched rods and filaments suggestive of actinomycetes. Using fluorescent antibody techniques these structures may be identified immediately as belonging to one of the traditional *Actinomyces* species. However, as specific antisera to all of the actinomycete species and serovars potentially present are usually not available, and as filamentous cells may be produced by various other bacteria, microscopy alone does mostly not suffice to demonstrate actinomycetes with adequate certainty.

Media and Procedures for Isolation and Cultivation from Natural Habitats Usually, plaque samples or similar specimens have to be dispersed before dilution and plating. Dispersal can be achieved by sonic or mechanical (Potter-type homogenizer or Vortex shaker) treatment. The homogeneous suspensions thus obtained can be diluted as usual using pre-reduced fluids. To grow fastidious and oxygen-sensitive members of the human indigenous microflora, all procedures should be carried out in an anaerobic chamber (glove box). If only actinomycetes are being considered, exposure to air for a shorter period of time does not significantly decrease the number of colony-forming units.

For cultivating fermentative actinomycetes, the various nonselective media recommended for examining clinical specimens before can also be used for ecological purposes. However, selective principles understandably facilitate their isolation and identification. On the other hand, selective media including those devised for fermentative actinomycetes so far may also inhibit certain strains of the species that are looked for, so that the qualitative and quantitative results obtained from such selective media may not nec-

essarily reflect the natural interrelations *in vivo* with sufficient accuracy.

The recipes for four different media devised for the selective isolation and enumeration of oral actinomycetes are given below. These media differ to some extent in their selectivity against other oral microbes and also in their inhibitory activity to individual *Actinomyces* species so that they should be selected according to the special aims of a particular study.

Partially Selective Medium for *A. viscosus* and *A. naeslundii* (CNAC-20 Medium; Ellen and Balcerzak-Raczkowski, 1975)

Add $3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$ to Columbia CNA agar base (Difco) prepared according to the manufacturer's instructions to give a final concentration of $20.0\text{ }\mu\text{g/ml}$. Autoclave. Incubate plates containing CNAC-20 medium at $36 \pm 1^\circ\text{C}$ in 90% air and 10% CO_2 to encourage growth of *A. viscosus* and *A. naeslundii* while inhibiting the more anaerobic actinomycetes and other Gram-positive anaerobes.

Selective Medium for Oral Actinomycetes (Beighton and Colman, 1976)

Basal Culture Medium (BYS medium)

Brain heart infusion broth	3.7 g
Yeast extract powder	0.5 g
Polyvinylpyrrolidone	1.0 g
Cysteine · HCl	0.1 g
Agar	1.5 g

Add these ingredients to 100 ml of distilled water and autoclave for 15 min at 121°C . Cool to 45°C and supplement with 5 ml of sterile horse serum.

Selective Enrichment Medium (FC medium)

NaF solution (25 mg/ml)	1.0 ml
Colistin sulfate solution (1 mg/ml)	0.5 ml

Sterilize the solutions separately by autoclaving at 121°C for 15 min before adding them to 100 ml of BYS medium.

Selective GMC Medium for *A. viscosus* and *A. naeslundii* (Kornman and Loesche, 1978)

Basal Medium

The enriched gelatin agar of Syed (1976) is recommended, but other complex media may yield similar results.

Selective Medium

Add Cadmium sulfate ($3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$) and Metronidazole to 1 liter of the basal medium to give final concentrations of $20\text{ }\mu\text{g/ml}$ and $10\text{ }\mu\text{g/ml}$, respectively.

Autoclave cadmium sulfate together with the basal medium. Cool to $45\text{--}50^\circ\text{C}$ and add a filter-sterilized solution of metronidazole aseptically.

The latter medium was reported to allow 98% recovery of *A. viscosus* and 73% recovery of *A. naeslundii*, while suppressing 76% of the total count of other oral organisms. *Propionibacterium propionicum* strains also grew quite well, whereas *A. israelii* and *A. odontolyticus* were inhibited (Kornman and Loesche, 1978).

Selective Medium for Detection and Enumeration of *A. viscosus* and *A. naeslundii* (CFAT Medium; Zylber and Jordan, 1982)

Trypticase soy broth (BBL)	30.0 g
Glucose	5.0 g
Agar	15.0 g
Cadmium sulfate ($3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$)	13.0 mg
Sodium fluoride (NaF)	80.0 mg
Neutral acriflavin	1.20 mg
Potassium tellurite	2.50 mg
Basic fuchsin	0.25 mg
Defibrinated sheep blood	50.0 ml

Dissolve ingredients in distilled water and dilute up to 1 liter. Adjust the final pH to 7.3.

This medium was reported to give considerably higher counts for *A. viscosus* and *A. naeslundii* than those from the FC and CNAC-20 media, respectively. The major interfering organisms on this medium were *Aerococcus* and *Rothia*, whereas FC and CNAC-20 media were less selective and supported growth of significant numbers of other oral organisms in the study of Zylber and Jordan (1982).

A different means of selectively isolating fermentative actinomycetes, especially *A. israelii* and *A. gerencseriae*, was described by Fritsche (1964).

Selective Isolation of *A. israelii* (Fritsche, 1964)

Suspend heavily contaminated materials such as feces in a suitable reduced transport or culture fluid (e.g., reduced transport fluid of Syed and Loesche [1972] or thioglycolate medium). Add 1 ml of the suspension thus obtained to 1 ml of toluene in a screw-cap tube. Agitate the tube on a mechanical shaker (high speed) for 20–25 min. Remove the watery suspension at the bottom of the tube carefully with a capillary pipette and add it to 10 ml of the same transport or broth medium. Remove remaining droplets of toluene on the surface of the medium with a Bunsen flame. Centrifuge so that the *Actinomyces* cells can settle, and streak the sediment onto nonselective agar media.

On first isolation, the colony morphology of the actinomycetes may be altered by this treatment but will become typical again upon subculture. *Actinomyces israelii* and possibly *A. gerencseriae* have been proven to survive this treatment in all instances. However, whether and to what extent the colony counts decrease after this procedure have not been investigated.

In a study of Lewis et al. (1995), the combination of mupirocin and metronidazole was used as selective principle for isolating *Actinomyces* species from clinical specimens. These authors reported that significantly more *Actinomyces* species were found on this selective medium than on corresponding nonselective media from both dental specimens and intrauterine contraceptive devices.

CULTIVATION Cell mass of *Actinomyces* species may be required in larger quantities for chemotaxonomic, molecular or physiologic analyses. Broth cultures usually applied for these purposes only give satisfactory results with species or strains which do not form persisting mycelial growth and which are comparatively rapid growers. Highly filamentous strains usually produce only scanty growth in fluid cultures unless the medium is continuously agitated or stirred during incubation. Furthermore, broth cultures are easily contaminated with propionibacteria from the skin of laboratory personnel. Growth of these contaminants may be facilitated by the slow and granular growth of certain actinomycetes and may be difficult to detect because the microscopic morphology of *Actinomyces* and *Propionibacterium* species is often very similar.

Mass cultures of filamentous *Actinomyces* species are therefore obtained most easily and economically when the membrane culture technique described in the section on Chemotaxonomy is used. In contrast, the more coryneform members of the genus *Actinomyces* can well be cultivated in fluid broth media.

The agar and broth media most suitable for growing fermentative actinomycetes together with certain supplements, which may be necessary, are described in detail in the sections on Isolation from Clinical Specimens and Natural Habitats.

PRESERVATION *Actinomyces* species may cause problems on continuous subcultivation, in particular when the growth medium contains fermentable carbohydrates that rapidly lead to toxically low pH values. Furthermore, cultures of these organisms tend to be readily contaminated, especially with propionibacteria, as mentioned above. Therefore, procedures that avoid both contamination and loss of viability should be used especially for long-term storage.

Cultures in routine use may be maintained by weekly transfer in thioglycolate broth containing 0.2% (v/v) rabbit serum or by monthly transfer on Fortner plates containing CC medium with 0.2% (v/v) rabbit or fetal bovine serum but no carbohydrates. Because of the risk of contamination of broth cultures, these have to be checked carefully for purity upon each transfer. On Fortner plates, accidental contaminants are usually detected more easily, but contamination problems may be caused by the *Serratia* strain simultaneously grown on the plate especially when the agar surface is too wet upon inoculation.

For longer preservation (up to 1 year) and long-term storage (several years to 10 years or longer), freezing or lyophilization is recommended (Slack and Gerencser, 1975; Schaal, 1986a; Schaal, 1986b). For freezing, 3–5 ml of

brain heart infusion broth in screw-capped tubes are inoculated with 0.1 ml of a fresh broth culture or a dense suspension of the organism in brain heart infusion broth prepared from a 3–7 day-old agar culture, and the inoculated broth is incubated at $36 \pm 1^\circ\text{C}$ for 3–5 (to 7) days under appropriate gaseous conditions (in air, in air with added CO_2 , or in an anaerobic jar) with the caps loosened. As soon as good growth is obtained, the caps are tightened and the tubes are placed in a freezer at -70°C .

For freeze-drying, the sediment of broth cultures or—preferably—biomass scraped from agar plates or dialysis membranes are suspended in sterilized skim milk or lyophilization medium and lyophilized by standard techniques (Slack and Gerencser, 1975; Schaal, 1986a; Schaal, 1986b).

Lyophilization Medium for Long-Term Storage of *Actinomyces* Species (Schaal, 1986b)

Brain heart infusion broth	1 part
Horse or fetal bovine serum	1 part

Mix and add sucrose to give a final concentration of 7% (w/v) in the whole mixture.

Using lyophilized cultures, Slack and Gerencser (1975) reported viability after 10 years of storage at room temperature. We were even able to revive most of the lyophilisates that had been stored for 20–30 years at room temperature. Frozen broth cultures will survive for at least 1 year.

Identification

Although *Actinomyces* species possess several differential characteristics potentially useful for their identification, they have been known for many years to be notoriously difficult to identify in medical or veterinary microbiology laboratories because morphology and traditional biochemical and physiological tests are often misleading and may be responsible for inadequate diagnoses or treatment failures. With the exception of serological methods, there is essentially no simple traditional test that will reliably differentiate *Actinomyces* species from morphologically or physiologically similar organisms. The same is true when individual isolates have to be identified to species level. It is for this reason that modern taxonomic techniques such as chemotaxonomy, fermentation end product analysis or molecular genetic methods have contributed so much to the classification and identification of these organisms. For the same reason, serological tests such as immunofluorescence procedures have widely been employed for identification purposes because they represent rapid, simple, and supposedly reliable diagnostic tools. However, more detailed serological as well as molecular studies (Schaal and Gatzert, 1985c;

Johnson et al., 1990; Stackebrandt and Charfreitag, 1990) have indicated that the antigenic and taxonomic structure even of those species that have been recognized for many years is more heterogeneous than previously thought. Therefore, identification results should not be based solely upon serology when a complete and reliable bacteriological diagnosis is to be achieved.

Morphological Characteristics

Morphological criteria were previously considered especially important for the identification of various actinomycetes because branching filamentous cells and mycelial growth appeared to be stable and reliable diagnostic characters. However, detailed morphological observations as well as modern taxonomic developments have shown that morphology may considerably vary within species and even between different cultures of the same strain, that morphological similarities do not necessarily reflect phylogenetic relationships, and that there is considerable overlapping between the microscopic and cultural characteristics of different species, genera and even families. Thus, microscopic or macroscopic examinations of clinical specimens or cultures usually do not allow reliable identification of the disease or the organisms present.

Nevertheless, cellular and colonial features may provide presumptive evidence for the systematic position of an unknown isolate and may therefore facilitate the selection of proper tests for rapidly and economically achieving a definite identification. When Gram-stained smears from clinical specimens show fragmenting filaments that are branching, irregularly curved and unevenly stained (Figs. 2 and 13), this is highly suggestive of an actinomycete infection or colonization, although not specific for a certain *Actinomyces* species because *Propionibacterium propionicum* and obligately aerobic actinomycetes (such as *Nocardia* or *Actinomadura* species) may be morphologically similar. On the other hand, fermentative actinomycetes often appear as diphtheroid rods or even coccoid forms resembling corynebacteria (Figs. 3 and 17), cutaneous propionibacteria, or streptococci, especially *Streptococcus mutans*, which tends to form elongated cells. Furthermore, *Actinomyces hordeovulneris* has been shown to produce L-phase variants spontaneously with coincident calcium deposition (Buchanan and Scott, 1984a) that are difficult to recognize as actinomycete elements.

Ørskov (Erikson, 1940) introduced the method of microscopically examining growing colonies of actinomycetes *in situ* on the agar surface. This method proved to be extremely useful for the presumptive recognition of these organisms, especially when early growth stages (after

Fig. 17. *Actinomyces meyeri*; Gram-stained smear from a mature colony (brain heart infusion agar, 14 days $36 \pm 1^\circ\text{C}$, and Fortner's method). Note the uneven uptake of the dye.

24–48 h of incubation) are examined. Lentze (1938a), using Fortner's method for cultivating actinomycetes, modified Ørskov's technique by using a long-distance, low-magnification objective (10 \times) to examine the plates from the bottom in transmitted light without opening them and thus without disturbing their semi-anaerobic microenvironment (Figs. 15 and 16). For applying this modification under routine conditions, the organisms are incubated anaerobically for 18–48 h on a suitable transparent agar medium (e.g., BHIA or CC medium) in glass Petri dishes with even-bottom surfaces. These are then searched microscopically for growth of filamentous colonies *in situ*. For more detailed morphological studies with higher magnifications, the following modification of the slide culture technique introduced by Schaal (Schaal, 1986a; Schaal, 1992b) is recommended.

Slide Culture Technique for the Detailed Microscopic Observation of Filamentous Actinomycete Microcolonies (Schaal, 1986a)

Preparation of Slide Cultures

Cover sterile glass slides with a thin layer of BHIA by briefly immersing one surface of the slide in melted BHIA of about 50°C . For solidification of the agar, transfer the slide to a sterile *moist* chamber at ambient temperature to prevent rapid drying of the thin agar layer. These chambers can be prepared from Petri dishes containing a bottom layer of sterilized filter paper, which has been moistened with sterile saline or distilled water. Perform all of the necessary manipulations under strict aseptic conditions, preferably in a clean bench.

Culture

Inoculate the agar-coated slides with the strain to be examined using a very thin glass filament. This can be prepared easily from a Pasteur pipette by softening the glass in a Bunsen flame and rapidly pulling both ends apart. The resulting filament is sterile and can be used immediately as an inoculating loop or needle. Depending on the organism to be examined, incubate the slide cultures inside their moistened dishes in an anaerobic or CO_2 -enriched jar for 5–20 h at $36 \pm 1^\circ\text{C}$.

Fig. 18. *Actinomyces israelii*; microcolonies with longer and shorter filaments and visible fragmentation; micrograph in situ in transmitted light (CC medium, 24 h at $36 \pm 1^\circ\text{C}$, and Fortner's method).

Fig. 19. *Actinomyces bovis*; small, irregular, but not filamentous microcolonies; micrograph in situ in obliquely transmitted light (CC medium, 24 h $36 \pm 1^\circ\text{C}$, and Fortner's method).

Microscopy

After incubation, remove the slides from the moist chambers and allow them to dry in air for 10–15 min. Thereafter, place 1 drop of lactophenol-cotton blue mounting fluid in the center of the agar layer and cover it with a clean cover slip. View under a microscope using phase-contrast equipment with objectives between 50 \times and 100 \times magnification (Fig. 6).

Lactophenol-cotton Blue Mounting Solution (Hendrickson, 1985)

Phenol crystals	20 g
Lactic acid	20 ml
Glycerol	40 ml
Distilled water	20 ml

Dissolve the ingredients by heating the flask in a hot-water bath. Add 0.05 g of cotton blue (Poirier blue).

Under such conditions, the microcolonies of fermentative actinomycetes may be highly filamentous without signs of fragmentation ("spider colonies"; Fig. 15), but the filaments may also be shorter although easy to identify (Fig. 18), or fragmentation may occur in very early growth stages.

Although there is some relation between species affiliation and the morphology of the microcolonies formed, this character is considerably variable and depends on growth conditions and medium composition as well as on the individual strain under examination. Filamentous microcolonies are usually not found in *A. odontolyticus*, *A. meyeri*, *A. georgiae*, *A. graevenitzii*, *A. radingae*, *A. turicensis*, *A. europaeus*, *A. neuii*, *A. funkei*, *A. radidentis*, *A. urogenitalis*, *A. cardiffensis*, *A. nasicola* and *A. hongkongensis*. The same is apparently true for the animal species *Actinomyces bovis* (Fig. 19), *A. denticolens*, *A. howellii*, *A. slackii*, *A. hyovaginalis*, *A. bowdenii*, *A. canis*, *A. catuli*, *A. suimastitidis*, *A.*

marimammalium and *A. coleocanis*, although the description of these species was primarily based upon 16S rDNA sequence data and a few physiological characters, whereas a detailed morphological characterization is as yet missing. Thus, among the members of the genus *Actinomyces* as currently defined, only *A. israelii*, *A. gerencseriae*, *A. naeslundii*, *A. viscosus*, *A. hordeovulneris* and possibly *A. oricola* usually or occasionally develop characteristic filamentous microcolonies.

Mature colonies may be observed with the naked eye or with a hand lens, but microscopy may provide more detailed information. Depending on experience and preference of the investigator, the following microscopic techniques may be applied: 1) standard microscopy in transmitted light using transparent media and a long-distance, low-magnification objective; 2) reflected light microscopy using a standard laboratory microscope, a long-distance objective, and an additional, external source of light (the path of which is adjusted to hit the area below the objective at an acute angle); and 3) reflected light microscopy using a dissecting, stereoscopic microscope. Irregularly raised, opaque colonies are best observed under reflected light. The examination of flat, smooth, and translucent colonies is easier, however, when the usual transmitted-light microscopy is applied.

Mature *Actinomyces* colonies may retain much of their mycelial appearance, especially in the periphery (Fig. 7). The typical "molar tooth" colonies of *A. israelii* (Fig. 9) and *A. gerencseriae* usually also show discernible peripheral filaments that radiate from the dense center of the colony. But in many strains of the primarily filamentous *Actinomyces* species, the actinomorphous edge may gradually get lost with further

Fig. 20. *Actinomyces israelii*; nearly completely fragmented macrocolony with a few single filaments left in the periphery; micrograph in situ in obliquely transmitted light (CC medium, 7 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

Fig. 22. *Actinomyces meyeri*; larger and smaller translucent macrocolonies with optically dark centers; micrograph in transmitted light (CC medium, 14 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

Fig. 21. *Actinomyces bovis*; small, comparatively dense, non-filamentous colonies; micrograph in obliquely transmitted light (CC medium, 14 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

development of the colony (Fig. 20). Most *Actinomyces* species, especially the majority of the recently described new ones, produce entirely smooth nonfilamentous colonies. These colonies may still be dense and opaque such as in *A. bovis* or *A. neuii* (Fig. 21), but they may also be flat and translucent such as in *A. odontolyticus* (Fig. 10) and *A. meyeri* (Fig. 22).

Acid End Product Analysis

As with strict anaerobes, the identification of end products from the fermentative metabolism of actinomycetes and related organisms provides additional criteria for allocation of an unknown isolate to the genus *Actinomyces*. Usually, gas-liquid chromatography (GLC) as described in the VPI Anaerobe Laboratory Manual (Holdeman et al., 1977) is used for this purpose, but more modern techniques such as high per-

formance liquid chromatography (HPLC) may give similar or even better results.

Determination of Fermentation End Products (Holdeman et al., 1977; Schaal, 1985b).

Culture Conditions

Inoculate peptone-yeast extract-glucose medium (PYG) or chopped meat-carbohydrate medium (CMC; Holdeman et al., 1977) heavily from an actively growing (3–7 days old, depending on the generation time of the test strain) agar culture (e.g., BHIA) by scraping off the growth using an inoculating needle or a sterile scalpel or by employing the dialysis membrane culture technique described in the section Chemotaxonomic Characters. Disperse the inoculum in the broth medium as homogeneously as possible by aspirating and expelling the colonial material several times with a Pasteur pipette. Incubate the inoculated tubes at $36 \pm 1^\circ\text{C}$ for 3–7 days under anaerobic conditions with added CO_2 (e.g., in an anaerobic jar or chamber), or until visible growth is obtained.

Preparation of Extracts for Analysis of Volatile Fatty Acids

Pipette 1 ml of the broth culture into a glass tube. Add 0.2 ml of 50% (v/v) H_2SO_4 , 0.4 g of NaCl and 1 ml of diethyl ether, and close the tube tightly with a screw cap lined with an inert polytetrafluoroethylene seal. Mix the components by inverting the tube gently about 20 times and allow the ether layer to separate from the aqueous phase either by placing the tube for a short time on the bench or by centrifugation. Pipette the upper ether layer, which contains the extracted volatile fatty acids, off the aqueous layer using a microliter syringe. Use this ether extract directly for gas chromatographic analysis, when the instrument is equipped with a flame ionization detector. When a thermal conductivity detector is used instead, remove the ether layer carefully from the tube and transfer it to another glass tube to which anhydrous 4–20 mesh CaCl_2 is added to equal about one-fourth of the volume of the ether in the tube. Close the tube and let it stand for about 5 min to remove most of the residual water.

Preparation of Extracts for Analysis of Nonvolatile Acids

Pipette 1 ml samples of the original culture into glass tubes as before, add 2 ml of methanol and 0.4 ml of 50% H₂SO₄, and seal the tubes tightly. Heat the mixture at 60°C in a heating block or water bath for 30 min so that methyl esters can form. Add distilled water (1 ml) and chloroform (0.5 ml), close the tube, and mix the contents by gentle inversion about 20 times. Any emulsion that may form can easily be broken by brief centrifugation. Aspirate the lower chloroform layer, which contains the methylated derivatives, directly from the bottom of the tube for gas chromatographic analysis using a microliter syringe.

Gas-liquid Chromatography

Comparatively simple and inexpensive instruments with either thermal conductivity or flame ionization detectors can be used. A temperature programming unit is not necessary but may facilitate the identification of the acids. Various types of column packings in glass or steel columns as well as capillary columns have been used successfully. FFAP or LAC-1-R 296 (WGA Düsseldorf, no. 6035) on Chromosorb-G as stationary phases has proved especially useful. The operating conditions routinely followed in the authors' laboratories are as follows: injection block, 160°C; detector block, 180°C; column oven programmed to rise from 80 to 160°C at a rate of 2°C/min; attenuation and carrier-gas flow rate depends on the types of columns and detectors used; and recorder speed may be 0.5 or 1.0 cm/min. Volatile and methylated products are run on the same column using the same operating conditions.

Procedure

Draw the ether or chloroform extracts (10 µl in case of use of a thermal conductivity detector and 1 µl in case of use of a flame ionization detector) into an appropriate microliter syringe, wipe off the outside of the injection needle, and inject the extract onto the column. Compare the elution times of the various compounds to be expected with those of a standard mixture (Holdeman et al., 1977) treated in the same way. Usually, qualitative interpretation of the results with visual comparison of the peak heights in the same chromatogram is sufficient for identification purposes. Alternatively, a more detailed semiquantitative analysis using a standard curve of peak heights can also be performed. After testing approximately 20 methylated samples, recondition columns by injecting about 10 µl of methanol.

Actinomyces species characteristically produce comparatively large amounts of succinic acid as compared to lactic and acetic acids (Table 10) when grown under anaerobic conditions with added CO₂. Morphologically similar strains of *Propionibacterium propionicum* or other *Propionibacterium* species can easily be differentiated by their production of major amounts of propionic acid, which is not produced by any member of the genus *Actinomyces*. Arcanobacteria produce considerable amounts of acetic and lactic acid, but small amounts of succinic acid, which may be difficult to detect. For comparison, some other morphologically similar genera are included in Table 10 to stress the differentiating

power of GLC end product analysis when applied to nonsporeforming Gram-positive, fermentative bacteria.

Chemotaxonomic Identification Procedures

Comparatively simple modifications of several chemotaxonomic procedures have been developed that are easily applicable for identification purposes under routine conditions (Becker et al., 1964; Alshamaony et al., 1977; Schaal, 1985b). This is especially true for the demonstration of diaminopimelic acid (A₂pm) or certain sugars in whole-cell hydrolysates, for the analysis of long-chain fatty acids in whole-cell extracts, and for the determination of cytoplasmic polypeptide patterns using sodium dodecylsulfate (SDS) polyacrylamide gel electrophoresis (PAGE). For clinical isolates that exhibit typical actinomycete morphology and which possess the basic physiological properties of fermentative actinomycetes, the application of chemotaxonomic methods is not necessarily required when reliable identification results are to be obtained. However, in case of morphologically and physiologically less characteristic isolates or in case of insufficient experience of the microbiologist with these organisms, the application of chemotaxonomic tests is strongly recommended unless suitable molecular methods are used to keep the number of misidentifications low.

Cell wall analysis of actinomycetes is undoubtedly a very valuable tool for the classification and identification of these organisms (Cummins and Harris, 1956; Cummins and Harris, 1958). However, even simplified techniques for the preparation of cell walls (Bousfield et al., 1985) still make the whole procedure so elaborate and time-consuming that most laboratories will not be able to perform such tests routinely. The use of whole cells instead of cell walls clearly saves time and labor, although it also reduces the amount of information that may be derived from these techniques. Thus, several simplified chemotaxonomic techniques have been used in the authors' laboratories for many years and have been found to be suitable for application in the routine diagnostic laboratory.

PREPARATION OF BIOMASS FOR CHEMOTAXONOMIC ANALYSES For most chemical analyses, comparatively large amounts of biomass are needed that should be free of contaminating material from the culture media. For many microbes, this requirement is readily fulfilled by using carefully washed cell mass from fluid cultures. Broth cultures of fermentative actinomycetes, however, are especially prone to microbial contamination, which is more easily controlled when the organisms are grown on solid media. On the other

^emeso-A₂pm present.

^fmeso- or no A₂pm present.

Modified from Schaal (1992).

hand, the substrate mycelium of *Actinomyces* species may be difficult to remove from an agar medium. To overcome these difficulties, the following simple and convenient procedure for obtaining noncontaminated cell mass of fermentative actinomycetes is recommended.

Preparation of Biomass of Fermentative Actinomycetes for Chemotaxonomic Tests (Schaal, 1985b)

Media

Brain heart infusion agar (BHIA) is satisfactory for essentially all of the organisms treated in this chapter. However, other media that provide good growth of the test organisms may also be used.

Membrane Culture Technique

Place autoclaved sheets of dialysis tubing on top of the agar surface of BHIA (in a Petri dish) and inoculate them with a heavy suspension of the test strain. Depending on its growth conditions, incubate the plates aerobically, under increased CO₂ tension, or anaerobically (anaerobic jar) at 36 ± 1°C until sufficient growth is obtained.

Cell Mass Preparation

After sufficient incubation, remove the dialysis membranes with the microbial growth on top from the agar

surface with a sterile forceps and transfer them to Erlenmeyer flasks containing either distilled water or saline and a few glass beads (~5 mm in diameter). Inactivate the organisms either by adding formaldehyde or by heating the flasks in a water bath at 75°C for 45 min. Wash growth off the membranes by shaking the flasks in a rotary shaker at 200–250 rpm and collect the cell mass by centrifugation. Wash the sediment in two changes of distilled water. Dry the cells by lyophilization (amino acid and sugar analyses may also be carried out on cells dried overnight in absolute ethanol).

AMINO ACID ANALYSIS One of the chemotaxonomic tests that are comparatively easy to perform is the demonstration of 2,6-diaminopimelic acid (A₂pm) in whole-cell hydrolysates (Schaal, 1985b). Although this test does not aid in the differentiation of *Actinomyces*, *Actinobaculum* or *Arcanobacterium* species from each other, it allows the reliable differentiation of *A. israelii* and *A. gerencseriae* from *Propionibacterium propionicum* (which are very similar morphologically) and of many of the new *Actinomyces* species from corynebacteria, propionibacteria, or listeriae (Table 10).

Demonstration of 2,6-Diaminopimelic Acid in Whole-Cell Hydrolysates (Schaal, 1985b)

Preparation of Extracts

Hydrolyze dried cells (1–5 mg) with 1 ml of 6N HCl in a sealed Pyrex tube at 100°C for 18 h. Cool and filter the hydrolysate through paper and wash the residue with 1 ml of distilled water. To remove most of the HCl, place the filtrate in a sand bath and evaporate the excessive fluid without burning the residue. Repeat this procedure 2 or 3 times after further addition of distilled water, or use a rotary evaporator to dry the filtrate under reduced pressure at 40°C.

Thin-layer Chromatography

After final washing, take up the extract in 0.3 ml of distilled water and spot 5 µl onto cellulose-coated thin-layer chromatography (TLC) plastic sheets (Merck 5577). For separating the amino acids, use ascending, single-dimensional TLC in a solvent system containing methanol-pyridine-10N HCl-water (80:10:2.5:17.5, v/v). A second development in the same direction and solvent mixture with intermediate air-drying can improve separation and identification of A₂pm.

Identification of the A₂pm Isomers

Visualize amino acid spots by spraying chromatograms with ninhydrin in acetone (0.1%, w/v) followed by air-drying and heating at 100–110°C for about 2 min. The isomers of A₂pm produce slowly moving, olive-green spots that fade to yellow; hydroxy-A₂pm has the lowest R_f value and is followed by *meso*-A₂pm and LL-A₂pm, respectively. Most of the other amino acids present in whole-cell hydrolysates give purple or blue spots. A standard solution containing *meso*-A₂pm (1%, w/v), which is usually contaminated with traces of LL-A₂pm, should always be included. DD-A₂pm is not separated from *meso*-A₂pm by this method.

SUGAR ANALYSIS The sugar patterns derived from TLC analyses of whole-cell hydrolysates are more difficult to evaluate than the simple A₂pm patterns. The various diagnostic sugars may originate from the cell wall, wall-associated structures, the cytoplasm, or from the culture medium when the cell mass has not been washed sufficiently before hydrolysis. Even trace amounts of contaminating sugars from the growth medium may become apparent when highly concentrated extracts are used. Nevertheless, TLC sugar patterns are especially useful for differentiating *Actinomyces* species.

Determination of Sugars in Whole-Cell Hydrolysates of Fermentative Actinomycetes (Schaal, 1985b)

Preparation of Extracts

Hydrolyze dried cells (50 mg) with 1 ml of 2N H₂SO₄ in a sealed Pyrex tube held at 100°C for 2 h. Neutralize the hydrolysate (pH 5.0–5.5 with methyl red as an internal indicator) by adding barium hydroxide (0.5 g) and shaking the mixture several times. Deposit the resulting precipitate and the remaining Ba(OH)₂ by centrifugation at 6000 rpm. Remove the supernatant carefully and evaporate to dryness either by lyophilization or on a rotary

evaporator under reduced pressure at 40°C. Take up the residue in 0.4 ml of distilled water and add pyridine (~1 ml). Mix and separate the pyridine phase from the aqueous phase by centrifugation at 6000 rpm. Transfer the upper pyridine layer, which contains the partially purified sugar extract, to a small glass vial and repeat the extraction procedure. Combine the pyridine extracts and concentrate the mixture in a stream of nitrogen at room temperature to give a final volume of approximately 0.3 ml.

Thin-layer Chromatography

Spot 5–10 µl of the concentrated pyridine extract onto cellulose-coated TLC aluminum sheets (Merck 5552) and separate the sugars by ascending, single-dimensional TLC using the following two solvent mixtures applied consecutively. Solvent 1: *n*-butanol-water-acetic acid (60:20:20, v/v), in which the chromatograms are run until the solvent front has reached about 6 cm. Remove the sheets from the tank and dry in air. Solvent 2: ethyl acetate-pyridine-water-acetic acid (100:35:25:5, v/v), in which the chromatograms are run three times, with intermediate air-drying, to an optimal distance of about 12 cm.

Identification of Sugars

Visualize the sugar spots by spraying chromatograms with an aniline-phthalate reagent (aniline, 2 ml; phthalic acid, 3.3 g; and water-saturated *n*-butanol, 100 ml), air-drying, and subsequent heating at 100°C for 2–5 min, whereupon hexoses give brown, pentoses red, and 6-deoxy sugars gray-green spots. The R_f values increase in the following order: galactose, glucose, mannose, arabinose, xylose, fucose, ribose, rhamnose and 6-deoxytalose. A mixture of these sugars (1%, w/v) in pyridine should be used as a standard.

In contrast to pathogenic aerobic actinomycetes, *Actinomyces* as well as *Arcanobacterium*, *Actinobaculum* or *Varibaculum* species do not contain detectable amounts of arabinose, xylose or madurose, and the same is true for propionibacteria, bifidobacteria, eubacteria and lactobacilli. The only filamentous, *Actinomyces*-like, fermentative organism that possesses arabinose in whole-cell hydrolysates is *Corynebacterium matruchotii*. The characteristic sugar patterns for *Actinomyces* species are summarized in Table 6 together with additional chemotaxonomic markers.

MYCOLIC ACID ANALYSIS AND OTHER CHEMOTAXONOMIC TESTS Mycolic acid analysis, which is very useful for differentiating aerobic actinomycetes and mycobacteria, only allows the separation of *Corynebacterium matruchotii* and other corynebacteria from members of the family Actinomycetaceae. Therefore, the simplified technique for analyzing mycolic acids is not described in detail in this chapter but has been published in the literature (Schaal, 1984a; Schaal, 1985b).

Additional useful criteria for identification may be derived from the analysis of long-chain fatty acids and isoprenoid quinones (Collins and Jones, 1981; Kroppenstedt, 1985) and from

electrophoretic whole-cell protein patterns (Jackman, 1985). However, as fatty acid analysis requires some experience and as the results may be influenced by media composition and growth conditions, the methods for fatty acid analyses are also not considered in detail in this chapter. For the identification of human isolates of *Actinomyces*, *Arcanobacterium* and *Actinobaculum* species, determination of whole-cell protein patterns is usually not necessary. Nevertheless, this technique may facilitate the reliable identification of certain animal isolates or some of the recently described new species of human origin.

Whole-cell protein patterns have been used widely to indicate intraspecies relatedness of newly described species (e.g., Pascual Ramos et al., 1997a; Collins et al., 2000b; Hoyles et al., 2000), thus avoiding more laborious DNA-DNA hybridization experiments. While easy to perform by an experienced laboratory, the disadvantage of this method is the lack of a universal cumulative database, thus preventing interlaboratory comparison of patterns.

Determination of Electrophoretic Polypeptide Patterns (Mauff et al., 1981; Dent and Williams, 1985)

Preparation of Protein Extracts

Wash about 1 g (wet weight) of the biomass (obtained as described) 3 times in distilled water with intermediate centrifugation at about 6000 g. Use one of the following extraction procedures. Procedure 1: Resuspend cells in distilled water and disintegrate the suspension in a Mickle shaker (Mickle Engineering Ltd., Gomshall, Surrey, UK) with glass beads (grade 12) for 1.5 h. Centrifuge at 17,000 g for 15 min and then at 150,000 g for 1 h to remove all traces of membranes. Procedure 2: Alternatively, resuspend the cells in 35 ml of 6.5 mM Tris · HCl (pH 8.4) containing 0.35 mg of DNase. Pass this suspension through a "French pressure cell" at 2200 psi. Centrifuge the crude extract thus obtained at 20,000 g for 15 min and subsequently at 48,000 g for 1 h. Concentrate the cell-free extract about 50 times using an Amicon B15 cell.

Electrophoresis

Electrophorese the cell-free extracts in 10% polyacrylamide-SDS gels as described by Swindlehurst et al. (1977) or using gradient polyacrylamide gel electrophoresis (G-PAGE; 4–30% gradient [Pharmacia]), 40 mM Tris-borate buffer (pH 8.4), 200 V, approximately 70 mA for 3 h at 4°C in an ORTEC flat bed electrophoresis apparatus (EGG Instruments, Munich, Germany; Mauff et al., 1981). After electrophoresis, stain the gels with 1% Coomassie brilliant blue (SERVA, Heidelberg, Germany).

Evaluation of Protein Patterns: Two Methods

Method 1. Use visual recognition and comparison of polypeptide patterns as a surveying technique in examinations also employing other taxonomic techniques. This simple and convenient procedure allows the identification of taxonomically identical or very similar strains in comparison to well-defined reference organisms, and it also allows the differentiation of isolates that give similar physiological test results but differ taxonomically.

Method 2. When the electrophoretic polypeptide patterns are produced under highly standardized conditions, scan in a microdensitometer and use the data to perform cluster analysis or computer identification (Kerstens and De Ley, 1975; Kerstens and De Ley, 1980; Mauff et al., 1981). More recent densitometric analysis, normalization and interpretation of protein patterns are often done with the Gelcompare software package (Applied Maths, Kortrijk, Belgium). Levels of correlation of patterns are usually expressed as percentages of similarity.

Apart from preparing cell-free, more or less purified soluble protein fractions, whole-cell samples produced by incubating a 6.4 M urea solution with an equal volume of packed *Actinomyces* cells may directly be used for PAGE (McCormick et al., 1985). The patterns thus obtained contain many more bands than those derived from cell-free extracts, but they appear to be reproducible and well suited for classification, identification or typing.

Methods for Testing Physiological Properties

Physiological markers, such as growth on different media, oxygen tolerance, CO₂ requirement, fermentation of carbohydrates, catalase activity, nitrate and nitrite reduction and others, have been used for many years to identify *Actinomyces* species but have recently been neglected in favor of DNA sequence data. As far as the genus level of these organisms is concerned, there is no doubt (Bowden and Hardie, 1973; Slack, 1974; Slack and Gerencser, 1975; Collins and Cummins, 1986; Schaal, 1986b) that physiological criteria need support from chemotaxonomic techniques, end product analyses or molecular methods to make them really effective (Tables 6, Table 7 and Table 10). On the species level, however, physiological tests still provide reliable and cost-effective means of identification when the procedures have been adjusted carefully to this special purpose and when a comparatively large battery of tests is used (Slack and Gerencser, 1975; Schofield and Schaal, 1980a; Schofield and Schaal, 1980b; Schofield and Schaal, 1981; Schaal and Schofield, 1984d; Schaal, 1986a; Schaal, 1986b).

A compilation of the traditional procedures for testing physiological markers of fermentative actinomycetes and related organisms was given by Slack and Gerencser (Slack and Gerencser, 1975). These authors proposed the use of thioglycolate fermentation base as mediator of fermentation tests.

Fermentation Tests of *Actinomyces* Species (Slack and Gerencser, 1975)

Basal Medium

Fluid thioglycolate medium without glucose 1 liter
or indicator

Yeast extract (glucose-free)	2 g
Bromocresol purple (1% aqueous solution)	2 ml

To this medium, add low molecular-weight carbohydrates (mono- and disaccharides) aseptically to give a final concentration of 1%; use other compounds at 0.5%.

It was shown that these and similar media, when used in amounts of 1 ml or more in regular test tubes, did not always yield satisfactory and reproducible results, especially when highly filamentous strains were to be identified. This became especially apparent in several numerical taxonomic studies in which analogous techniques were used (Melville, 1965; Holmberg and Hallander, 1973b; Holmberg and Nord, 1975a). These problems are obviously due to the inadequacy of the inoculum size and growth rate of the organisms compared to the volume of the substrate-containing medium. In contrast, the results obtained from miniaturized test procedures (Schofield and Schaal, 1979a; Schofield and Schaal, 1979b; Schofield and Schaal, 1980a; Schofield and Schaal, 1980b; Schofield and Schaal, 1981; Buchanan et al., 1984b) indicate that these modifications of the traditional physiological tests appear to be much more suitable for testing of fermentative actinomycetes because in this case the inoculum-substrate relation is more favorable for slowly and inhomogeneously growing organisms. Among the various commercial miniaturized identification systems, only the Minitek differentiation system (BD) was shown to be applicable to the identification of all members of the genus *Actinomyces* (Schofield and Schaal, 1979a). However, since this system is no longer available on the market, the following modification can be used.

Modified Miniaturized System for Testing Acid Production from Carbohydrates by Fermentative Actinomycetes and Related Organisms (Schofield and Schaal, 1979a; Schofield and Schaal, 1980a; Schofield and Schaal, 1981)

Basal Medium

Thioglycolate broth without glucose or indicator, supplemented with 0.2% (w/v) yeast extract.

Preparation of Carbohydrate-containing Filter Paper Disks

Soak sterile blank filter paper disks (Oxoid) in 3% (w/v) solutions of the various test carbohydrates (filter-sterilized under aseptic conditions) and dry by lyophilization.

Test Procedure

Prepare the inoculum from 4–7 day-old cultures at $36 \pm 1^\circ\text{C}$ on BHIA or CC medium by removing colony material carefully without adhering agar particles, and suspend it in basal medium (thioglycolate) using a platinum loop or a sterile spatula. For strains whose colonies adhere firmly to the agar, use the dialysis membrane culture technique described for chemotaxonomic analyses. Homogenize the suspensions using a Vortex mixer or a

similar mixing device after addition of a few sterile glass beads to the tube. Add 2–3 drops of a densely turbid suspension thus obtained to each well of a microtiter tray with flat bottoms already containing one of the sugar-impregnated disks.

Cover the trays with a plastic tape or a plastic cover (when using a tape, perforate it over each well with a sterile injection needle to allow gaseous exchange), and incubate for 2–3 days in an anaerobic jar at $36 \pm 1^\circ\text{C}$. After incubation, add 1 drop of a 0.2% (w/v) solution of bromothymol blue to each well. Acid production is indicated by a yellow color of the indicator; when the carbohydrate has not been fermented, the color of the indicator is green. A blue-green or blue color is usually due to contamination of the inoculum or a test strain not belonging to the genus *Actinomyces*.

Determination of Nitrate and Nitrite Reduction and Urease and Arginine Dihydrolase Activities by Fermentative Actinomycetes (Schofield and Schaal, 1980b; Schofield and Schaal, 1981)

Basal Medium

Bacto peptone (Difco)	5.0 g
Yeast extract (Difco)	3.0 g
Glucose	0.5 g
K ₂ HPO ₄	2.0 g
Agar	0.5 g

Dissolve in and dilute up to 1 liter with distilled water. Adjust the pH to 6.8 and sterilize the medium by autoclaving at 121°C for 15 min.

Test Procedure

Add the test substrates to basal medium from filtered solutions to obtain the following final concentrations:

Sodium nitrate	0.1%
Sodium nitrite	0.005%
Urea	0.5%
Arginine	0.5%

Pipette the various solutions of the test substances in basal medium into the wells of microtiter trays in volumes of 0.15 ml. Inoculate with suspensions of the test organisms in basal medium containing no agar, seal the wells with a plastic tape, which is perforated as described above, or use a plastic cover. After an incubation of 3–4 days, assess the formation (nitrate reduction) or disappearance (nitrite reduction) of nitrite by adding one drop of the usual nitrite reagent (8.0 g of sulfanilic acid + 1000 ml of 5N acetic acid and 5.0 g of α -naphthylamine + 1000 ml of 5N acetic acid, mixed in equal amounts immediately before use). The development of a brick-red color immediately after addition of the reagent indicates the presence of nitrite. If no color develops in the nitrate reduction test, add a small amount of fine granular zinc (which would reduce nitrate to nitrite when the former is still present in the well) to differentiate between negative nitrate reduction and reduction of both nitrate and nitrite. Assess urease activity and deamination of arginine by means of the ammonia released into the medium. To detect the presence of ammonia, add 1–2 drops of Nessler's reagent to the wells whereupon a heavy, dark yellow-to-ochre precipitate forms immediately. Slowly developing precipitates may be derived from other ingredients of the test medium and must be considered as negative test results.

The test for esculin hydrolysis may be performed using a standard esculin hydrolysis test medium dispensed into microtiter wells as described for the nitrate reduction test. Further characters useful for the identification of fermentative actinomycetes and related organisms can be derived from carbon source utilization tests. However, in organisms such as the fermentative actinomycetes, which require complex media for good growth, these tests are comparatively difficult to perform and only provide reproducible results when the basal medium is carefully adjusted (Schofield and Schaal, 1979b). Therefore, results from the latter tests were not included in Tables 11 and 12, which summarize the physiological characters most useful for the identification of *Actinomyces* species.

Tests for enzymatic activities detectable by means of "chromogenic" or "fluorogenic" substrates were also shown to possess differential power when applied to the classification and identification of fermentative actinomycetes and related organisms (Schofield and Schaal, 1981; Casin et al., 1984; Kilian, 1987; Lämmle and Blobel, 1988; Brander and Jousimies-Somer, 1992; Maiden et al., 1996; Sarkonen et al., 2001), but they were again found to be difficult to standardize because many of the enzymes which might be detected in this way are inducible, so that the test result highly depends on the nature of the growth medium used for preparation of the inoculum. Furthermore, enzyme reactions are not equally suited for the identification of all of the *Actinomyces* species described so far (Brander and Jousimies-Somer, 1992).

Various commercial test systems, which are based upon such enzyme tests completely or in part, have been used for the characterization and identification of *Actinomyces* species, especially of the recently described new taxa. These systems include the API ZYM, the RapID ANA II, the API 20 anaerobes, the API 20 Strep, the API rapid ID 32 Strep, the API CORYNE, the API (RAPID) CORYNE (bioMérieux), and the Rosco diagnostic tablets (Rosco, Taastrup, Denmark) systems. Furthermore, a test based on 4-methylumbelliferyl (4-MU) derivatives of various substrates has also been applied successfully to the phenotypic identification of these organisms (Sarkonen et al., 2001).

4-MU Fluorogenic Substrate Tests (Whiley et al., 1990; Maiden et al., 1996)

4-MU substrates such as (4-MU)- α -L-arabinoside, 2'-(4-MU)- α -D-N-acetylneuraminic acid and many others for the detection of, e.g., α -L-arabinosidase or sialidase may be purchased from Sigma Chemical Co. Ltd., UK.

Preparation of Substrate Solutions

Dissolve the various substrates in a minimum volume of dimethyl sulfoxide and dilute in 50 mM *N*-tris

(hydroxymethyl)methyl-2-aminoethanesulfonic acid buffer (pH 7.5) (TES buffer, Sigma) to a final concentration of 100 μ g/ml.

Inoculum Preparation

Grow the bacteria for 2 days, usually in an anaerobic jar, at $36 \pm 1^\circ\text{C}$ on BHIA, remove colonies from the medium using sterile swabs and place the growth in TES buffer; adjust the suspension to an optical density at 620 nm of 0.1 (approximately 10^8 organisms per ml).

Tests for Enzyme Activity

Mix 20 μ l of substrate solution with 50 μ l of bacterial suspension in a flat-bottomed clear microdilution plate well and incubate at $36 \pm 1^\circ\text{C}$ for 3 h. Visualize substrate degradation (release of 4-methylumbelliferone) by viewing the trays on an ultraviolet (UV) transilluminator or with a hand-held UV lamp under long-wave UV rays (366 nm). Positive reactions are indicated by a bright blue-white fluorescence. Use positive (e.g., *Prevotella oris* ATCC 33573) and negative (e.g., *Veillonella parvula* ATCC 10790) and noninoculated controls.

Miniaturized multitest systems such as the API 20 anaerobes (Casin et al., 1984), the API 20 Strep (Morrison and Tillotson, 1988), the API rapid ID 32 Strep (Nikolaitchouk et al., 2000), the API CORYNE (Hoyles et al., 2001), and the API (RAPID) CORYNE (Funke et al., 1997b) systems contain carbohydrate fermentation reactions in addition to the enzyme tests, or they consist exclusively of fermentation reactions such as the API 50 CH system (bioMérieux). When applied to the identification of fermentative actinomycetes, reliability and reproducibility of the identification results highly depend upon the growth characteristics of the individual test strain, especially as far as acid production from carbohydrates is concerned. Species and strains that form predominantly smooth, nonfilamentous growth, so that homogeneous cell suspensions can easily be prepared, may give satisfactory results (Funke et al., 1997b). This is particularly true for most of the recently described new *Actinomyces*, *Actinobaculum* and *Arcanobacterium* species. On the other hand, highly filamentous, slowly fragmenting strains such as members of the traditional species *A. israelii*, *A. gerencseriae* or *A. hordeovulneris* are often misidentified or cannot be identified at all when using these systems because key reactions among the carbohydrate fermentation tests tend to be falsely negative. Furthermore, it has been shown (Hall et al., 2003a) that the patterns of physiological characters produced by different test systems may differ considerably for a given actinomycete strain. This is true not only when comparing conventional tests with commercial test systems but also when comparing different commercial

From Dent and Williams (1986c), Schaal (1986b), Collins et al. (1993), Pascual et al. (1999), and Hoyles et al. (2000, 2001a, b, c, 2002).

systems, even from the same manufacturer. In a recent comparative study of four commercial systems (RapID ANA II, Rapid ID 32 A, RapID CB Plus, and BBL Crystal) for identification of *Actinomyces* species and some closely related bacteria (Santala et al., 2004), a strikingly poor applicability of these systems to the fermentative actinomycetes was found that relates not only to the new but also to the "classical" species of this bacterial group. Updating these kits to improve their performance as proposed by Santala et al. (2004) clearly requires both extension of the respective databases and inclusion of additional characters with more appropriate differential power.

In view of the problems discussed above, the physiological characteristics listed in the diagnostic Tables 11 and 12 and in Tables 8 and 9 should be used with care because only some of the data were derived from identical or comparable techniques. The latter is particularly true for all of the *Actinomyces* species included in volume 2 of *Bergey's Manual of Systematic Bacteriology* (Schaal, 1986a) and for *A. hordeovulneris*, which were tested using modifications of the Minitek® system (Schofield and Schaal, 1979a; Schofield and Schaal, 1979b; Schofield and Schaal, 1980a; Schofield and Schaal, 1980b; Schofield and Schaal, 1981; Buchanan et al., 1984b). The data for all of the other *Actinomyces* species were taken from the respective original descriptions in which the various API systems were preferentially applied. In Tables 8 and 9, which summarize many of the physiological characters available so far for *Actinomyces* species, this methodological aspect could not be taken into account, so that this table is merely a compilation of the rough literature data rather than an exact physiological description of the respective species.

Because of difficulties in standardizing the various physiological tests, it appears by no means appropriate to construct a flowchart for identifying fermentative actinomycetes and related organisms that is solely based upon physiological reactions (Sarkonen et al., 2001). When branching points such as esculin hydrolysis, urease activity, β -*N*-acetylglucosaminidase (NAG) activity, or α -fucosidase activity are used in these flowcharts, standardization problems will inevitably lead to misidentifications.

For the same reason, biotyping has gained no practical importance for differentiating *Actinomyces* species below the species level. In general, little information is available on the typing possibilities of these organisms. A bacteriophage typing system has not been developed. Lytic phages have only been isolated for *A. viscosus*, both from domestic sewage and human dental plaque (Delisle et al., 1978; Delisle et al., 1988;

Tylenda et al., 1985). These phages were found to exhibit high host-cell specificity and productively infected only certain *A. viscosus* strains. However, the suitability of such phages for probing surface components of human oral actinomycetes has been discussed (Tylenda et al., 1985; Delisle et al., 1988). Thus, only serological and molecular typing methods appear as yet suitable for being applied to fermentative actinomycetes.

Serological Identification and Typing

The early papers on the serology of fermentative actinomycetes (see Slack et al., 1951 and Slack et al., 1955) already indicated that the differentiation of these organisms is possible by means of serological methods. However, the traditional serological procedures such as agglutination or complement fixation tests presented methodological problems. Thus, serology only became widely applicable for diagnostic and scientific identification and typing purposes after the introduction of fluorescent antibody techniques into the field of actinomycete classification and identification (Slack et al., 1961).

Since then, other serological methods, including gel precipitation, enzyme immunoassay and immunoelectrophoresis, have also been used, and some of the antigens of *Actinomyces* species have been isolated and characterized in some detail (Ayakawa et al., 1983; Schaal, 1986a; Happonen et al., 1987; Firtel and Fillery, 1988). The latter investigations showed that antigens common to several different species are generally present, but they also showed that species-specific, partial antigens are usually strong enough to allow reliable serological identification when absorbed or properly diluted antisera are used (Slack and Gerencser, 1975; Schaal and Gatzert, 1985c). Firtel and Fillery (1988), investigating the antigenic structure of *A. viscosus* and *A. naeslundii* using a set of 18 monoclonal antibodies against whole cells of these species, found 11 different antigenic determinants which were arranged in a complicated mosaic. Although some of the monoclonal antibodies appeared to be useful for identification, not all of the antigenic groups delineated within the *A. viscosus* and *A. naeslundii* complex could be identified with comparable reliability. Nevertheless, the antigenic profiles defined by these 18 monoclonal antibodies corresponded at least to some extent to the distinctions made within this group of actinomycetes by DNA hybridization experiments (Johnson et al., 1990).

For routine application, a simple fluorescent antibody (FA) procedure has been devised by Slack and Gerencser (1975).

Direct Fluorescent Antibody Test (Slack and Gerencser, 1975)

Preparation of Smears

For clinical material, make two smears of the material on a clean glass slide containing two marked circles. Fix air-dried smears by flooding with methanol for 1 min. Pour off the alcohol and allow the slide to air-dry. For cultures (from a suspension of the organism obtained by centrifugation of a broth culture or from an agar culture), make smears on glass slides, air-dry, and gently heat-fix.

Staining Procedure

Place one drop of conjugated specific antiserum on each smear and incubate the slide in a moist chamber for 30 min at room temperature. Pour off excess conjugate and wash the slide in two changes of pH 7.2 buffer (FTA hemagglutination buffer, BD) for 5 min each. Counterstain in 0.5% Evans blue for 5 min. Remove excess Evans blue by dipping the slide briefly into distilled water. Then, wash the slide in two changes of pH 9.0 buffer for 1 min each. Allow smears to air-dry. Place one drop of buffered glycerol mounting fluid (9 parts chemically pure glycerol, 1 part pH 9.0 buffer) on each smear and cover it with a coverslip. For examination with a microscope equipped for FA work, preferably use 54× oil-immersion or 50× water-immersion objectives.

For routine use of this technique, it is disadvantageous that fluorescein isothiocyanate (FITC)-labeled specific antisera to *Actinomyces* species are not available except for antisera to *A. israelii* and *A. naeslundii* (Biological Reagent Section, Centers for Disease Control, Atlanta, Georgia, United States). Thus, most antisera have to be prepared and conjugated by the user. To avoid part of this elaborate and time-consuming work, which is required for the application of the direct fluorescent antibody (FA) technique, Schaal and Pulverer (1973) have described an indirect FA staining procedure that provides similarly specific identification results and is even more sensitive than the direct FA modification. In this method, commercially available, FITC-conjugated goat antisera to rabbit globulins are used. Nevertheless, the specific antisera to the various *Actinomyces* species still have to be produced in the diagnostic laboratory by immunization of rabbits. The following immunization scheme has proved especially effective in the authors' laboratory.

Immunization Scheme for Preparing Antisera to Whole-Cell Antigens of Fermentative Actinomycetes (Schaal and Pulverer, 1973; Schaal and Gatzert, 1985c)

Preparation of Antigens

Biomass of the reference strains is produced using the dialysis tubing membrane technique on BHIA as described for chemotaxonomic tests or BHI broth cultures when nonfilamentous species are to be examined. Incubate plates anaerobically (anaerobic jar) or aerobically with added CO₂ (5–10%) depending on the species examined at 36 ± 1°C for 7 days. Remove the dialysis membranes from the agar surface with sterile forceps. Transfer them

to Erlenmeyer flasks containing sterile saline with added phenol (1%, v/v) and wash the cell mass off the membranes by shaking with glass beads. Centrifuge broth cultures and resuspend the sediment in sterile saline with added phenol. Inactivate the cell suspensions thus obtained by heating at 60°C for 20 min in a water bath. Homogenize them in a Potter tissue homogenizer, and adjust to a concentration of 20 mg of wet weight per ml.

Immunization Scheme

Most types of ordinary laboratory rabbits can be used for immunization. Cross-bred animals often give best immune responses. Use the following schedule: First week—day 1, 1.5 ml, i.m.; day 3, 0.5 ml, i.v.; day 4, 1.0 ml, i.v.; day 5, 1.5 ml, i.v.; and day 7, 1.5 ml, i.m. Second week—day 10, 1.5 ml, i.v.; and day 13, 1.5 ml, i.v. Fourth week—day 22, test for antibody production. Possibly use cardiac puncture for obtaining the antiserum. If the test for antibody production (indirect FA) shows titers below 1 : 1000, make 2–4 (to 6) booster injections at half-weekly intervals. Lyophilize the antisera (obtained in the usual way, by cardiac puncture in ether anesthesia and subsequent separation from fibrin and blood cells) in 1-ml aliquots until use.

For antiserum production, at least the type and reference strains (see Schaal, 1986a and Schaal, 1986b) of the classical *Actinomyces* species should be used. However, these strains apparently do not cover completely the antigenic variation present in these taxa, especially in the species *A. israelii* (Ayakawa et al., 1983; Schaal and Gatzert, 1985c), and they do not include the recently described new species whose antigenic structure and relationships are largely unknown.

Because of the higher sensitivity of the indirect immunofluorescence technique, use of absorbed antisera is usually necessary for convenient and reliable identification to the species level. Crossreacting activities can easily be removed by traditional sorption procedures using the respective cellular antigens at concentrations of 60 mg wet weight per ml of serum and a final dilution of the absorbed antiserum of 1 : 40. Alternatively, highly diluted (depending upon the homologous antibody titer) antisera or comparative end point titrations can be used.

Indirect Fluorescent-antibody Procedure for Identifying *Actinomyces* species (Schaal and Pulverer, 1973; Schaal and Gatzert, 1985c)

Preparation of Smears

Prepare smears as described for the direct modification.

Staining Procedure

Place 1 drop of absorbed specific rabbit antiserum on each smear and incubate the slide in a moist chamber for 30 min at ambient temperature. Pour off excess antiserum and wash the slide in two changes of pH 7.2 buffer (FTA hemagglutination buffer, BD) for 5 min each. Allow the slide to briefly air-dry. Place 1 drop of FITC-conjugated goat antiserum to rabbit immunoglobulins on the same smear and incubate again in a moist chamber for about 30 min at room temperature. Pour off excess conjugate

Fig. 23. *Actinomyces israelii*; indirect immunofluorescence with an absorbed rabbit antiserum to *A. israelii* and FITC-labeled goat anti-rabbit immunoglobulin; incident-light fluorescence micrograph.

and wash the slide in two changes of pH 7.2 buffer. Counterstain the smear in 0.5% Evans blue for 5 min. Remove excess Evans blue by dipping the slide briefly into distilled water and wash the slide in two changes of pH 9.0 buffer for 1 min each. Allow the smear to air-dry. Place 1 drop of buffered glycerol mounting fluid on each smear and cover it with a coverslip. For examination with a microscope equipped for FA work, use a 50× water-immersion or an analogous oil-immersion objective.

Provided that staining procedure and reagents have been sufficiently standardized (Holmberg and Forsum, 1973a; Schaal and Gatzer, 1985c), immunofluorescence techniques allow rapid and comparatively reliable identification of at least most of the classical *Actinomyces* species (Fig. 23). They also allow the recognition of the serovars of those classical species for which serovars were defined. However, these techniques are especially valuable for clinical microbiological laboratories because the methods are directly applicable to clinical specimens as well as to cultures (Slack and Gerencser, 1975). Furthermore, the identification and enumeration of filamentous organisms in dental plaque, gingival crevice, or cervicovaginal secretions can be achieved by these methods. It should be kept in mind, however, that antigenically aberrant strains and hitherto unknown or insufficiently characterized serotypes or species may be lost or misidentified if immunofluorescence procedures are applied as the sole means of demonstration and identification (Ayakawa et al., 1983; Schaal and Gatzer, 1985c).

Antifibril antisera have been used to identify the subgroups delineated within the species *A. viscosus* and *A. naeslundii* by numerical phenetic methods, using either immunofluorescence or whole bacterial cell agglutination (Masuda et al., 1983; Ellen and Grove, 1985a).

Serological Diagnosis of Actinomycete Infections

Because of difficulties in obtaining suitable clinical specimens and isolating and identifying pathogenic actinomycetes, there has always been a demand for diagnosing actinomycotic infections by means of serological techniques. Although several different serological methods have been tested for their suitability for this purpose, the results have usually not been satisfactory.

The only detailed serological studies that appear to indicate at least a certain diagnostic value of serology in actinomycete infections were performed by Holmberg and co-workers (Holmberg et al., 1975b; Holmberg, 1981; Persson and Holmberg, 1984). Using counterimmunoelectrophoresis or crossed immunoelectrophoresis, these authors reported sensitivities of 83–86% (for their test system when comparing cultural and histological with serological results) and comparatively high specificities, although a certain number of patients suffering from nocardiosis, tuberculosis, candidiasis or aspergillosis also gave positive reactions (Holmberg, 1981). According to the authors' experience with immunofluorescence and immunoassay procedures for more than 20 years, these techniques are only able to detect long-lasting and generalizing actinomycotic processes with sufficient reliability, but they are nearly useless for diagnosing localized infections. Therefore, these serological tests cannot be used for excluding or confirming the diagnosis actinomycosis when suitable specimens for cultural examinations are difficult or impossible to obtain, such as in cases of deep-seated actinomycotic abscesses of the internal organs including the female genital tract. The nature and importance of precipitation reactions against *A. israelii* antigens in uterine secretions still remain to be definitely clarified (Persson and Holmberg, 1985).

Natural human antibody response to *Actinomyces* antigens has also been studied in relation to caries and periodontal disease (Levine et al., 1984; Levine and Movafagh, 1986; Morinushi et al., 1989). From these studies, it was concluded that such natural antibodies might exert a protective effect against caries and subgingival plaque formation. Animal studies (Haber and Grinnell, 1989) appear to support these conclusions. In addition, these antibodies, especially to *A. viscosus* or *A. naeslundii* antigens, are obviously very common in otherwise healthy individuals and they tend to interfere with the serological tests for actinomycosis because *Actinomyces* species usually have one or more antigens in common, so that cross-reactions are frequently observed.

Identification and Typing Using DNA Technologies

DNA:DNA hybridization studies may be performed according to the procedures devised by Johnson et al. (1990) and Dent and Williams (1985). Barsotti et al. (1987) described a rapid technique for isolating DNA from fermentative actinomycetes. This method may facilitate DNA work with these organisms, which are difficult to lyse gently and effectively.

While these classical quantitative methods are mainly used to determine the threshold value for species differentiation, DNA probe hybridization methods (i.e., dot blot, subtraction, and checkerboard hybridizations) have been applied to identify *Actinomyces* species. Among others, these approaches have been applied to identify oral actinomycetes thriving in supra- and subgingival habitats (Ximenez-Fyvie et al., 1999) and in periapical endodontic lesions of asymptomatic teeth (Gatti et al., 2000; Sunde et al., 2000), *A. hyovaginalis* in necrotic samples of pigs (Storms et al., 2002), to differentiate *A. israelii* and *A. gerencseriae* strains (Jauh-Hsun et al., 1999), or to detect and identify *Mobiluncus* species (Påhlson et al., 1992).

Other molecular methods used in identification are based on characterization of the rRNA gene, such as direct sequence analysis of this gene (Clarridge and Zhang, 2002; Storms et al., 2002; Woo et al., 2002), sequence analysis of the rRNA spacer region (Storms et al., 2002), and restriction analysis of amplified genes (amplified rDNA restriction analysis [ARDRA]; Hall et al., 1999). The advantage of using sequences for reliable identification was demonstrated by the study of Woo et al. (2002). While an unidentified isolate from pelvic actinomycosis was identified as *Propionibacterium granulosum* by the VITEK (ANI) system (99% confidence), the API system (20A) affiliated this strain with 78% confidence to the *A. meyeri/odontolyticus* cluster; 16S rRNA gene sequence analysis, however, indicated absolute match with the sequence of *A. odontolyticus*. Kiyama et al. (1996) developed a system for detecting *Actinomyces* species based upon non-radioactive riboprobes coupled with polymerase chain reaction (PCR). Using a portion of the sialidase gene of *A. naeslundii* as a target for a digoxigenin-labeled probe, the system was reported to be three orders of magnitude more sensitive in detecting specific chromosomal DNA than a conventional riboprobe system.

Brailsford et al. (1999) used repetitive extragenic palindromic PCR (REP-PCR) for typing 56 *A. israelii* and 46 *A. gerencseriae* strains derived from nine active root caries lesions. Their results indicated that the genotypes of both *A. israelii* and *A. gerencseriae* populations were

heterogeneous (i.e., not sharing the same REP-PCR patterns) within individual lesions.

Ecology

Knowledge of the biologic role of members of the genus *Actinomyces* in their natural habitats under healthy conditions is still fragmentary. The same is true for their interactions with other members of the respective indigenous microflora. Analysis of the biologic functions of fermentative actinomycetes in the lower intestine is difficult because their numbers are strikingly lower than those of other members of the normal bowel flora. In the upper intestinal tract, which until recently was considered to harbor no or only small numbers of cultivable microorganisms, the significance of actinomycetes and other aerobic and anaerobic bacteria remains to be defined in general.

The occurrence of *Actinomyces* species in the female genital tract raises several questions. The first is whether these microbes are able to colonize the internal female genital organs without presence of a foreign body such as an IUD. Although several authors have demonstrated *Actinomyces* species—and *Propionibacterium propionicum*—in genital secretions of women who did not wear IUDs or vaginal pessaries, two observations suggest that their presence may reflect change in the physiological balance in the female genital tract: 1) these organisms directly adhere to the device and its thread (Fig. 24), often buried in a thick biofilm, and 2) the actinomycetes disappear or become difficult to isolate after removal of the IUD. This change might have medical implications, although a considerable percentage of those women do not show any

Fig. 24. Mixed actinomycotic flora cultured from the thread of an intrauterine contraceptive device. Small actinomycete colony (arrow) among a variety of other bacterial colony forms; micrograph in situ in obliquely transmitted light (brain heart infusion agar, 14 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

subjective or objective symptoms of disease (Mao and Guillebaud, 1984; Pine et al., 1985; K. P. Schaal, unpublished observations).

The occasional recovery of *Actinomyces* species from the uninfected eye is probably accidental and does not imply that these organisms constitute normal inhabitants of the conjunctiva or the tear organs given the physiological connection between conjunctiva and upper respiratory tract via the lacrimal canaliculi.

Much more information has accumulated in recent years concerning the role of actinomycetes in the oral cavity. Although most of these studies were performed to clarify the pathogenesis of caries, periodontal disease, or gingivitis, some of the possible disease-contributing factors may also be present without signs of impairment and thereby represent at least one aspect of the biologic functions of these organisms in their natural environment.

Studies of the ability of fermentative actinomycetes to colonize the oral cavity, to resist natural and artificial cleaning mechanisms, and to utilize organic compounds present in the oral cavity as nutritional sources, as well as the complex interactions between various members of the oral microflora and between them and the mucosal and dental surfaces, have been extensive. A total of 1.9×10^7 fermentative actinomycete cells were estimated per gram wet weight of human dental calculus (Collins et al., 1973). Subgingival plaque samples of different groups of periodontal patients who had been successfully treated and maintained were populated by higher proportions of Gram-positive bacteria including *Actinomyces viscosus* and *A. odontolyticus* (Asikainen et al., 1987), whereas in patients with active periodontitis, spirochetes, *Porphyromonas* or *Bacteroides* species predominated, indicating that the actinomycetes were commensals rather than pathogens in these particular conditions (Loesche et al., 1985).

Recent studies on the oral colonization with *Actinomyces* species in 2–24 month healthy infants have provided a more detailed insight into the composition of the actinomycete oral flora during this early period (Sarkonen et al., 2000). Within the first two years, the frequency of the total actinomycete flora increased from 31% to 97%. *Actinomyces odontolyticus* appeared to be the most prominent colonizer at 2, 6, 12, 18, and 24 months of age. *Actinomyces naeslundii* (a species regarded as one of the pioneer colonizers of tooth surfaces) was also commonly encountered but not before the age of one year (Kolenbrander et al., 1999). The recently described species *A. graevenitzii* was also rather regularly identified in the mouths of children (Sarkonen et al., 2000), and *A. viscosus*, *A. gerencseriae*, *A. israelii* and *A. georgiae* were found

in the oral cavity of children and in gingival crevices of periodontally healthy adults (Cato et al., 1984; Johnson et al., 1990).

A special ecological situation arises when natural teeth are replaced by artificial implants, particularly by complete dentures. The subgingival microflora under these conditions may resemble qualitatively the plaque flora of healthy individuals but also that of progressive periodontitis (Wahl and Schaal, 1989). When comparing the microbial colonization of two types of connection parts of an IMZ-implant-supported Dolder bar, Wahl et al. (1992) found significant differences between the flora of elastic and titanium devices. The number of aerobically growing bacterial species, as well as that of oral capnophils and anaerobes, was higher on the elastic than on the titanium elements. However, essentially no difference in actinomycete colonization between the connection elements was seen: *A. viscosus* clearly predominated while *A. israelii*, *A. gerencseriae* and *Propionibacterium propionicum* were rarely identified in both locations.

Probably the most important feature that allows actinomycetes to colonize the oral cavity and even the smooth surfaces of teeth (and that prevents them from being washed off by salivary flow) is their ability to attach directly to the tooth surfaces, to adhere to mucosal cells and to co-aggregate with other microbes present in the same place. The simplest of these attachment mechanisms is the production of sticky extracellular or cell-associated polymers (glycocalyx), especially of levan, dextran, glycogen, and *N*-acetylglucosamine-rich slime polysaccharides, which facilitate attachment to enamel, artificial denture materials and even glass. *Actinomyces viscosus* (Howell and Jordan, 1967; Pabst, 1977; Miller et al., 1978b; Hamilton and Ellwood, 1983; Imai and Kuramitsu, 1983; Ooshima and Kuramitsu, 1985; Komiyama et al., 1988) and *A. naeslundii* (Slack and Gerencser, 1975; Komiyama et al., 1988) were shown to produce these polymers.

Important cell-associated structures of oral actinomycetes (including several *Actinomyces* species), which mediate both interbacterial aggregation and adhesion processes, are the so-called “surface fibrils” or “fimbriae.” These fimbriae were found to consist of high molecular-weight proteins with some carbohydrate and up to 14.3% nitrogen (Cisar and Vatter, 1979; Masuda et al., 1983). That attachment and coaggregation might be due to such fimbrial proteins was first suggested by the finding that proteolytic enzyme or heat treatment impaired coaggregation between *A. naeslundii* or *A. viscosus* on the one hand and *Streptococcus sanguinis* or *Streptococcus mitis* on the other hand (Ellen and Balcerzak-Raczkowski, 1977; McIntire et al., 1978).

Soon it became apparent that a lectin-like mechanism was involved in some of these interbacterial coaggregations. McIntire et al. (1978) reported that the coaggregation between *A. viscosus* T14V and *Streptococcus sanguinis* 34 required a protein or glycoprotein on *A. viscosus* and a carbohydrate on *S. sanguinis*. (This coaggregation, as well as the binding of *A. viscosus* to glycoprotein-coated latex beads and its hemagglutinating properties, was specifically inhibited by lactose, β -methyl-D-galactoside and D-galactose, but not (or only weakly) by α -methyl-D-galactoside, melibiose, maltose, cellobiose, sucrose and a number of monosaccharides. (Costello et al. 1979; Heeb et al. 1985) found that *A. naeslundii* and *A. viscosus* were able to agglutinate human AB and horse erythrocytes.) This agglutinating property was enhanced by pretreatment of the red blood cells with neuraminidase and specifically inhibited by the compounds mentioned before. Furthermore, it was suggested that the actinomycetes were able to prime erythrocytes and human buccal epithelial cells for hemagglutination or attachment by removing sialic acid to expose more penultimate β -galactosides on the surface of the cells. Thus, neuraminidase removal of terminal sialic acid and lectin-like binding to exposed β -galactoside-associated sites on the erythrocytes appeared to be responsible for the hemagglutinating and adherence capabilities of *A. naeslundii* and *A. viscosus* (Saunders and Miller, 1983).

Other studies have shown that *A. viscosus* possesses two different types of fimbriae: type 1 fimbriae are involved in the attachment of this organism to saliva-coated hydroxyapatite, whereas type 2 fimbriae mediate the lactose-inhibitable, lectin-dependent coaggregation with *Streptococcus sanguinis* (Cisar et al., 1984a; Cisar et al., 1984b; Cisar et al., 1988; Clark et al., 1986; Mergenhausen et al., 1987). Using specific polyclonal and monoclonal antibodies, Ellen et al. (1989) demonstrated that anti-type 2 antibodies bound to antigens on long fibrils, whereas anti-type 1 antibodies were mostly localized close to the cell body or on shorter appendages.

A. naeslundii has type 2 fimbriae, which contain a lectin with a specificity similar to but not identical with that of *A. viscosus* (McIntire et al., 1983; Cisar et al., 1984a; Cisar et al., 1984b). These β -galactoside-reactive fimbrial lectins have specificities similar to those of certain plant lectins (Brennan et al., 1984) and bind to glycosphingolipids (gangliosides and globosides) and a 160-kDa surface glycoprotein of mammalian cells, particularly epithelial cells (Brennan et al., 1986; Brennan et al., 1987). Cloning, sequencing, and expression of type 1 and type 2 fimbrial antigens of *A. viscosus* and of type 2 fimbriae of *A. naeslundii* in *Escherichia coli* have

been successful (Yeung et al., 1978; Donkersloot et al., 1985; Yeung and Cisar, 1988), so that a more detailed insight into the structure of type 1 and type 2 fimbriae could be obtained.

The intergeneric bacterial coaggregations and the adhesion to oral tissues are mediated not only by fimbrial lectins but clearly also by several other mechanisms (Mizuno et al., 1983; Gibbons, 1989). Furthermore, coaggregation of bacteria in the oral cavity is a complex phenomenon that involves not only direct cell-to-cell interactions of coaggregating cell types, but also the formation of bridges (especially by *Bacteroides/Prevotella/Porphyromonas* species and fusobacteria) that mediate coaggregations between two primarily noncoaggregating cell types (Kolenbrander et al., 1985; Weiss et al., 1987; Kolenbrander, 2000). Bacteria that serve as coaggregation bridges may use different adhesion mechanisms for binding to the different partners (Weiss et al., 1987), and binding-site competition does occur between organisms with similar coaggregation mechanisms (Kolenbrander et al., 1985). In addition, plaque formation is influenced by inhibitory activities exerted by some oral bacteria against other organisms (e.g., *Prevotella melaninogenica* against *Actinomyces* species; Takazoe et al., 1984; Tompkins and Tagg, 1986).

Saliva influences the adherence to teeth and interbacterial coaggregation and may have antibacterial properties; it may also serve as a source of nutrients for oral microorganisms (Kolenbrander and Phucas, 1984; De Jong et al., 1986; Koop et al., 1989). A unique family of salivary components, the so-called "acidic proline-rich proteins" (PRPs), is especially involved in non-lectin attachment mechanisms. These compounds adsorb to hydroxyapatite surfaces, thereby undergoing conformational changes that enable oral bacteria such as *A. viscosus* to bind to the PRPs (Gibbons et al., 1988; Gibbons, 1989). In addition, zeta potential, surface energy, and hydrophobic and electrostatic interactions may influence bacterial adhesion to uncoated and saliva-coated human enamel and dentine (Gibbons and Etherden, 1983; Wheeler et al., 1983; Clark et al., 1985; Weerkamp et al., 1988).

All of these factors finally result in an extremely complex ecological system (i.e., the oral biofilm or the oral microbial-plaque community; Kolenbrander, 2000). This system is characterized by special mutualistic relationships (Palmer et al., 2001) that not only can determine whether the partners grow preferentially in the planktonic or in the biofilm state, but also may be responsible for the special spatial arrangement and associative behavior of the partners (Guggenheim et al., 2001) and for resistance to detrimental factors such as oxygen contact. Bradshaw et al. (1998) showed convincingly that

coaggregation-mediated interactions between *Fusobacterium nucleatum* and other species facilitated the survival of strict anaerobes in an aerated environment.

Thus, apart from physical interactions (such as coaggregation and coadhesion), physiological and metabolic interactions also facilitate communication between members of the genetically diverse biofilm flora (Kolenbrander, 2000). One of the most obvious consequences of the latter is the production of various organic acids. They evolve from the fermentative metabolic processes that occur *in vivo* as well as *in vitro* and may be strong enough to lower the pH values locally (Ellen and Onose, 1978). Acid production may lead not only to enamel demineralization and cell alteration, but also to influences on growth and metabolism of other oral microorganisms (McDermid et al., 1986). These influences may be attributed to different sensitivities of the various oral microbes to low pH values (Phan et al., 2000), to the ability of certain bacteria such as veillonellae to utilize the end products of the actinomycete metabolism for their nutrition in the sense of a food chain (Distler et al., 1980), or to the simultaneous utilization of several carbon and energy sources (Van der Hoeven et al., 1984). In *A. viscosus* and *Lactobacillus casei*, differences in acid tolerance can be related to the activity of proton-translocating membrane ATPases (Bender and Marquis, 1987).

A variety of enzymes involved in the initial dissimilation of exogenous carbohydrates or the energy yielding glycolytic pathway has been identified in *Actinomyces* species; thus, α - and β -galactosidases, β -glucuronidases, α - and β -glucosidases, β -xylosidases and α -fucosidases have been detected in several *Actinomyces* species (Fiehn and Moe, 1984; Tables 8 and 9). In addition, invertase activity has been demonstrated in both *A. naeslundii* (Miller, 1974) and *A. viscosus* (Palenik and Miller, 1975; Kiel et al., 1977b). And *A. viscosus* and *A. naeslundii* were shown to possess extracellular and cell-associated enzymes able to degrade levans of microbial origin (Miller and Somers, 1978a; Igarashi et al., 1987), indicating that additional types of food chains do exist which make the nutrition of some actinomycetes partially independent of exogenous carbohydrate sources from the host's diet.

The relative numbers of actinomycetes in the oral environment may be influenced by inhibitory factors released by other bacteria (Rogers et al., 1978), by fluorides or other measures for preventing caries (Beighton and McDougall, 1977; Johansen et al., 1997; Phan et al., 2000), or by eating habits of the host (Pfister et al., 1984; Minah et al., 1985). Furthermore, an active role of actinomycete bacteriophages with high host

cell specificity in the oral microbial ecology has been discussed (Tylenda et al., 1985). In any case, the qualitative and quantitative composition of the oral microflora differs between the saliva (in the planktonic state) and the mucosal and tooth surfaces (both in the biofilm state) and even varies from tooth to tooth and at different sites on a single tooth. It has been reported that Gram-positive, facultative and anaerobic bacteria constitute 15–20% of the cultivable flora in saliva and on the tongue, 40% of that in plaque, and 35% of that in gingival crevice (Socransky and Manganiello, 1971). Actinomycetes amounted to about 40% of the cultivable organisms in plaque (Loesche et al., 1972; Ellen et al., 1985b; Brown et al., 1986; Nyvad and Fejerskov, 1989). The incidence of individual species has been given above, although these figures (or the relative incidences) vary considerably between different authors and different groups of test persons.

Finally, the oral microflora changes with age and life circumstances of the host. Anaerobic bacteria are generally found in large numbers during the period of life when natural teeth are present (Socransky and Manganiello, 1971; Russell and Melville, 1978). Before dentition and after loss of all teeth in later life, the counts for anaerobes and so for actinomycetes are lower (Kostecka, 1924; Rosenthal and Gootzeit, 1942; Berger et al., 1959; Loesche, 1960). The age distribution of actinomycotic infections as well as studies on the oral colonization with *Actinomyces* species in early childhood (Sarkonen et al., 2000) indicates, however, that these organisms are present during the whole lifetime of their hosts.

Epidemiology

For the region of Cologne, Germany, annual morbidity of human cervicofacial actinomycoses averaged 1 : 40,000 (Schaal, 1979a) or 1 : 71,000 (Lentze, 1970). In contrast, Durie (1958) estimated 10 cases of the disease occurred annually in the population of Sydney/Australia, and Hemmes (1963) reported one case per year occurred in 119,000 inhabitants of Holland. Thus, differences in the frequency with which cervicofacial processes are diagnosed appear to be the chief reason for differences in the anatomic distribution of this disease. This, in turn, might reflect a difference in the approach to the bacteriological diagnosis of cervicofacial infections in Germany versus other parts of the world. On the other hand, there are indications that the cervicofacial form has also been decreasing recently in Germany.

Because of their endogenous origin, human actinomycoses are world-wide in distribution.

Nevertheless, the sex distribution of the disease is skewed toward males. Most tabulations of sex ratios (see Slack and Gerencser, 1975) agree with our data (Pulverer, 1974; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal, 1981a; Schaal and Lee, 1992c; Pulverer et al., 2003), which indicate that the ratio is about three to four males per one female. However, this proportion only applies to sexually mature patients suffering from cervicofacial infections; practically no sex distribution differences can be demonstrated before puberty and in advanced age (Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal and Lee, 1992c; Pulverer et al., 2003), so that the proportions vary with age from 0.9:1 to 4.0:1. Nevertheless, actinomycosis may be acquired during the whole lifetime (Slack and Gerencser, 1975; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b), as the age of patients with bacteriologically confirmed actinomycosis was found to range from 28 days to 82 years, with the highest incidence observed in males 20–40 years old and females 10–30 years old (Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Pulverer et al., 2003).

As far as caries and periodontitis are concerned, some epidemiological hints are given in the sections on Ecology and Pathogenicity. Nearly nothing is known about the epidemiology of infections due to species other than *A. israelii*, *A. gerencseriae*, *A. naeshlundii* or *A. viscosus*. The same is true for animal *Actinomyces* infections, although the classical bovine actinomycosis appears to occur sporadically world-wide.

Pathogenicity

Since the description of the first member of the genus *Actinomyces* (Bollinger, 1877), fermentative actinomycetes have been known to be able to produce characteristic and potentially severe inflammatory diseases in man and animals. These pathogenic species belong to the normal indigenous microflora of their hosts, so that they must be considered facultative pathogens, which only invade tissue under certain facilitating conditions and are usually not transmissible (Lentze, 1938a; Lentze, 1938b; Lentze, 1969; Slack and Gerencser, 1975; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal, 1979a; Schaal, 1986a; Schaal, 1996; Schaal, 1998; Schaal and Beaman, 1984b; Schaal and Pulverer, 1984c; Schaal and Lee, 1992c). Therefore, in a sense, these organisms may be called opportunistic pathogens, although they differ from classical opportunists in that they generally do not require an immunocom-

promised host for invasiveness but only proper local starting conditions.

Human Diseases due to *Actinomyces* Species

HUMAN ACTINOMYCOSIS The most typical disease entity caused by fermentative actinomycetes is called “actinomycosis,” a name that dates back to the first extensive description of the disease in animals by Bollinger (1877) and in humans by Israel (1878). As currently recognized, actinomycosis is a subacute-to-chronic, granulomatous inflammatory syndrome that gives rise to suppuration, abscess formation, and draining sinus tracts during its course (Slack and Gerencser, 1975; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal, 1979a; Schaal, 1996; Schaal, 1998; Schaal and Beaman, 1984b; Fig. 25). In the beginning, actinomycotic lesions may appear as slowly progressing infiltrations or as acute abscesses or phlegmons. Advanced processes show a typical and dangerous preference to penetrate the tissue irrespective of natural organ borders (Lentze, 1969; Lentze, 1970) and a tendency to remit and exacerbate with and without antibiotic therapy (Lentze, 1969; Slack and Gerencser, 1975; Schaal, 1979a; Schaal, 1996; Schaal, 1998; Bennhoff, 1984; Schaal and Beaman, 1984b).

Sulfur Granules In 10–25% of the cases, depending on the course of the disease (Pulverer

Fig. 25. Chronic cervicofacial actinomycosis in a 45-year-old man presenting with multiple fresh and older abscesses, non-healing incision wounds, and sinus tract as well as central scar formation.

and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal, 1979a; Schaal, 1981a; Schaal, 1996; Schaal, 1998; Schaal and Beaman, 1984b), the purulent discharge from actinomycotic processes contains macroscopically visible (up to 1 mm in diameter), yellowish to reddish to brownish particles. These particles represent a conglomerate of filamentous actinomycete microcolonies formed *in vivo* and surrounded by tissue-reaction material, especially polymorphonuclear granulocytes (Fig. 12). These diagnostically typical structures, which, when derived from human infections, exhibit on microscopic examination a cauliflower-like appearance at low magnification and clusters of interwoven branching filaments with radially arranged peripheral hyphae at higher magnification (Lentze, 1969; Slack and Gerencser, 1975; Schaal, 1979a; Schaal, 1981a; Schaal, 1984a; Fig. 13), were originally designated "Drusen" in Harz's first description of *Actinomyces bovis* (Harz, 1877), and this name was subsequently used also for corresponding particles in human infections although the morphology of human and animal Drusen is not completely identical. In the English literature, these particles are usually referred to as "sulfur granules," a term which solely relates to their yellow color but not to a strikingly high sulfur content. Such granules, when encountered in tissue sections, and less frequently also in purulent discharge, often show a club-shaped layer of hyaline material on the tips of peripheral filaments which can aid in the differentiation of *Actinomyces* granules from macroscopically similar particles of various other microbial and nonmicrobial origins.

Clinical Pictures The source of typical human actinomycoses is nearly always endogenous (i.e., the causative agents are derived from the patient's own indigenous mucosal microflora). Therefore, the disease primarily develops in tissue adjacent to the mucosal surfaces that harbor the microorganisms. Clinically, these predilection sites are mostly referred to as cervicofacial, thoracic, abdominal or pelvic. In the extensive material that has been collected at the Hygiene Institute of the University of Cologne by Lentze, Pulverer, and Schaal and in the German National Consulting Laboratory for Actinomycetes at the Institute for Medical Microbiology and Immunology of the University of Bonn by Schaal over a 50-year period, cervicofacial actinomycoses have been observed most frequently (in 96% of more than 4000 cases examined; Pulverer et al., 2003). In the same series of cases, thoracic infections only amounted to about 2% and abdominal and pelvic manifestations to about 1% (Pulverer and Schaal, 1984a;

Pulverer and Schaal, 1984b; Schaal and Pulverer, 1984c; Schaal, 1988).

Although the above-mentioned data reflect the situation for Germany as a whole rather than that for the Cologne and Bonn region only, the anatomical distribution observed by these German authors differs considerably from that reported for other countries, especially for the United States (Slack and Gerencser, 1975), where 40–50% of human actinomycotic infections were found to be located in thoracic and abdominal sites. These differences are still difficult to explain but may relate in part to the higher overall incidence of the cervicofacial form of the disease in Germany (see Epidemiology).

Cervicofacial actinomycoses predominantly develop in the soft tissue around the mandible, but they may also be found adjacent to the maxilla or may extend to the orbita, sinuses, ear or neck (Pape et al., 1984; Olson et al., 1989). Even primary actinomycosis of the thyroid gland has been observed (Dan et al., 1984). In contrast to typical animal actinomycoses, which usually affect the skeleton, osseous involvement is rarely seen in humans. Nevertheless, actinomycotic osteitis or osteomyelitis of the mandible, the maxillae, and even the skull and the cervical vertebrae may be observed sporadically (Yenson et al., 1983; Gupta et al., 1986; Vannier et al., 1986).

Actinomycotic infections of the central nervous system (CNS) are also rare and may either develop hematogenously from distant sites (lung, abdomen and pelvis) or by direct extension from contiguous foci such as ear, orbital cavity, sinus or cervicofacial lesions (Smego, 1987; Nithyanandam et al., 2001). Such CNS infections predominantly present as brain abscesses but may also become manifest as meningitis, meningoencephalitis, subdural empyema, or epidural abscess (Peacock et al., 1984; Prager et al., 1984; Tvede et al., 1985; Smego, 1987; Tsai et al., 2001).

Thoracic actinomycoses usually have a history of preceding cervicofacial lesions, which descend along the cervical soft tissue to the mediastinum, or of aspiration, but they may also develop hematogenously. Diagnosis is mostly difficult to establish and many cases reported in the literature as well as the authors' observations indicate that the disease is primarily often misdiagnosed as bronchial carcinoma until abscess or sinus tract formation and the detection of sulfur granules suggest the proper diagnosis (Suzuki and Delisle, 1984; Masters et al., 1985; Massart et al., 1986; Philipsen et al., 1988; Schaal, 1996; Schaal, 1998; Fig. 26). Early diagnosis is usually only possible when aggressive methods of obtaining suitable specimens for microbiological examination (such as transtracheal aspiration of bronchial secretions and transthoracic needle biopsy or

Fig. 26. Thoracic actinomycosis in a 64-year-old man presenting as massive infiltration of the right upper lung accompanied by a huge subcutaneous abscess over the right shoulder; X-ray photograph.

abscess puncture) are applied (Orloff et al., 1988). The nature and clinical relevance of a disease that some authors have termed “endobronchial actinomycosis” remain to be definitely clarified (Jin et al., 2000).

Like pulmonary and thoracic infections, actinomycoses of the abdomen and small pelvis tend to be misdiagnosed as carcinoma. This is especially true for infections of the rectum and for pelvic actinomycoses following the use of IUDs. Abdominal actinomycoses often follow appendicitis, abdominal trauma, or bowel surgery, may be located retro- or intraperitoneally (Adachi et al., 1985; Wohlgemuth and Gaddy, 1986; Levine and Doyle, 1988), and may involve a variety of organs such as the colon (Heer et al., 1986), rectum (Stein and Schaal, 1987), perianal tissue (Shimada et al., 1986; Gayraud et al., 2000), gallbladder (Van Steensel and Kwan, 1988), and liver (Mongiardo et al., 1986; Forgan-Smith et al., 1989; Logan et al., 1989).

The incidence of pelvic actinomycoses appears to be increasing in recent years, and this increase is probably related to the colonization of the cervical canal, the *cavum uteri*, and contraceptive devices by fermentative actinomycetes. Such infections may remain restricted to tissue in the small pelvis (uterus, Fallopian tubes, and ovaries) but may also spread continuously or hematogenously to the liver and other intraabdominal organs (Lininger and Frable, 1984; Persson and

Brihmer, 1986; Brihmer et al., 1987; Shurbaji et al., 1987; O'Connor et al., 1989; Eibach et al., 1992). Even involvement of the placenta and of the urinary bladder presenting with sulfur granules in the urine has been observed (Wajszczuk et al., 1984; Zakut et al., 1987).

Primary actinomycoses of the skin and the extremities are rare and usually have a history of trauma resulting from human bites or fist fights (“punch actinomycosis”), thus representing the only exogenously acquired forms of the disease. Hematogenous dissemination to the soft tissue, the bones, or joints of the extremities has also been observed (Mesgarzadeh et al., 1986; Reiner et al., 1987; Blinkhorn et al., 1988), and even a total hip arthroplasty was found to be infected (Strazzeri and Anzel, 1986).

Generalization of actinomycotic processes with the formation of multiple abscesses in various organ systems is rare nowadays and usually only occurs when diagnosis and proper treatment have been delayed (Schaal and Pulverer, 1984c; Schaal et al., 1984e). The same is true for the dissemination of the disease via the lymphatic vessels with involvement of the regional lymph nodes (Amrikachi et al., 2000).

Opportunistic actinomycotic infections in immunocompromised patients are not common. However, actinomycoses following osteoradionecrosis of the jaw (Happonen et al., 1983), radiotherapy of a tonsillar carcinoma (Spapen et al., 1989), renal transplantation (Kammoun et al., 2001), as well as infections in AIDS patients (Gresser et al., 1988) indicate that immunocompromising conditions or treatment methods may also be able to initiate actinomycotic processes, particularly when they result in tissue damage adjacent to the mucous membranes.

Etiopathology The etiology of human actinomycoses has been difficult to elucidate, especially because diseases are almost never caused by classical facultatively pathogenic actinomycetes demonstrable by isolation in pure culture. Nearly all of the typical human actinomycotic lesions appear as polymicrobial infections in which the pathogenic *Actinomyces* acts as the “guiding organism” (Lentze, 1948; Lentze, 1969; Lentze, 1970) that is responsible for the typical clinical picture and course of the disease. The concomitant bacteria, which are always present but may vary in number and species composition, are obviously necessary to strengthen the comparatively low invasive power of the actinomycetes (Lentze, 1948; Lentze, 1953; Lentze, 1969; Lentze, 1970; Holm, 1950; Holm, 1951; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal, 1979a; Schaal, 1981a; Schaal, 1985a), either by providing low oxygen tension in the tissue or by sup-

plementing the guiding organism with toxic, necrotizing or otherwise aggressive extracellular products.

In about 50% of the cases examined in the laboratories in Cologne and Bonn, the mixed actinomycotic flora was composed of facultative to strict anaerobes together with aerobically growing microorganisms. In the other half of the cases, solely anaerobes were cultured from the purulent exudate (Lentze, 1969; Pulverer, 1974; Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal, 1979a; Schaal, 1985a; Schaal, 1988; Schaal and Lee, 1992c; Pulverer et al., 2003). Among the aerobically growing concomitant bacteria, *Staphylococcus epidermidis*, *Staphylococcus aureus* and α - and β -hemolytic streptococci were the most prevalent. The carboxyphilic and anaerobic component of the concomitant actinomycotic flora consisted of carboxyphilic ("microaerophilic") streptococci (*S. milleri* group), anaerobic streptococci such as *Peptococcus*, *Peptostreptococcus*, *Anaerococcus*, *Peptoniphilus*, *Finegoldia*, *Micromonas* or *Atopobium* species, black-pigmented Bacteroidaceae, other *Bacteroides* and *Prevotella* species, fusobacteria, cutaneous propionibacteria, *Leptotrichia buccalis*, *Eikenella corrodens*, *Capnocytophaga* species, and *Actinobacillus actinomycetemcomitans*. The latter organism was encountered in about 25% of the cases examined and, when present, usually led to a particularly chronic and serious course of the disease.

Although the concomitant bacteria constitute a necessary factor in the pathogenesis of human actinomycosis in the sense of synergistic companions, the development of typical chronically progressive actinomycotic lesions is impossible without the presence of the pathogenic actinomycete species. However, as the concomitant bacteria also belong to the resident or transient indigenous microflora of human mucous membranes, localized anaerobic infections other than actinomycosis do occur at the same predilection sites and may be difficult to distinguish clinically from true actinomycoses, especially in their early manifestations. In addition, clinical specimens may be contaminated with actinomycetes from the mucosal surface or may contain two different actinomycete species, and this may cause confusion concerning their etiological role.

These considerations illustrate the problems that exist when posing the question: which oral actinomycetes produce typical human actinomycoses and which do not? Numerous reports in the world literature leave no doubt that *Actinomyces israelii* is the most characteristic and most common cause of human actinomycosis. Out of 1042 strains of fermentative actinomycetes isolated

in the authors' laboratories from typical clinical conditions over a 27-year period and identified to species level, 588 (56.4%) were found to belong to the species *A. israelii* (Schaal and Lee, 1992c). The number of isolates identified as *A. gerencseriae*, which had formerly been subsumed under the designation *A. israelii*, serovar 2, amounted to 259 (24.9%) in this study, so that these two classical human pathogens were found to be responsible for 81.3% of the actinomycosis cases examined. Several other *Actinomyces* species such as *Actinomyces naeslundii*, *A. viscosus*, *A. odontolyticus* and *A. meyeri* have also been recovered from actinomycotic processes (Schaal and Lee, 1992c), but their pathogenic potential under these clinical circumstances has not been documented with similar certainty and has chiefly been deduced from comparatively small numbers of isolations or case reports. However, there is no doubt that another fermentative filamentous bacterial species, *Propionibacterium propionicum* (formerly *Arachnia propionica*), is also able to produce typical human actinomycoses (Gerencser and Slack, 1967; Brock et al., 1973; Slack and Gerencser, 1975; Conrad et al., 1978; Schaal and Lee, 1992c). According to the authors' observations, this species was encountered in 3–4% of the infections suspected to be of actinomycotic nature (Pulverer and Schaal, 1978; Pulverer and Schaal, 1984a; Pulverer and Schaal, 1984b; Schaal, 1979a; Schaal, 1985a; Schaal, 1988; Schaal and Lee, 1992c; Pulverer et al., 2003).

LACRIMAL CANALICULITIS AND OTHER EYE INFECTIONS Lacrimal canaliculitis is another, less severe and usually noninvasive infection that may be caused by fermentative actinomycetes. Branching, filamentous organisms in lacrimal concretions were already described by Ferdinand Cohn (1875). More recent examinations showed that these filamentous microbes can be identified as *Actinomyces israelii*, *A. gerencseriae*, *A. naeslundii*, *A. viscosus*, *A. odontolyticus* or *Propionibacterium propionicum* (Pine and Hardin, 1959a; Pine et al., 1960; Ellis et al., 1961; Buchanan and Pine, 1962; Slack and Gerencser, 1975; Jones and Robinson, 1977; Blanksma and Slijper, 1978; Schaal and Pulverer, 1984c; Schaal, 1988; Schaal and Lee, 1992c; Schütt-Gerowitt et al., 1999; Takemura et al., 2002). According to the authors' experience, the incidence of *Propionibacterium propionicum* is much higher in lacrimal canaliculitis than in cervicofacial and other actinomycotic infections, in that this organism was isolated from lacrimal concretions approximately as frequently as was *A. israelii* (Schaal and Lee, 1992c; Schütt-Gerowitt et al., 1999). Other inflammatory processes of the eye such as conjunctivitis, dacryocystitis, keratitis,

hordeolum and granuloma, or even intraocular infections, may also be due to *Actinomyces* species (Schaal, 1988; Schaal and Lee, 1992c; Schütt-Gerowitt et al., 1999). However, it appears that in these conditions species other than *A. israelii*, *A. gerencseriae* and *Propionibacterium propionicum* are the predominant etiologic agents. Furthermore, two different *Actinomyces* species such as *A. israelii* plus *A. naeslundii* may occasionally be recovered simultaneously from the same eye specimen (Schaal and Pulverer, 1984c).

OTHER INFECTIONS DUE TO *ACTINOMYCES* SPECIES

There is growing evidence that *Actinomyces* species are most likely to play an etiological role in a variety of other human inflammatory processes (*nonspecific infections*) that do not present as clinically characteristic actinomycoses. This is especially true for most of the recently described new species, but also for some of the classical ones. Information about the pathogenicity of *Actinomyces naeslundii* and *A. viscosus* as far as invasive infections are concerned is still comparatively meager, although these organisms may be recovered from clinical specimens rather frequently (Coleman and Georg, 1969; Gerencser and Slack, 1969; Karetzky and Garvey, 1974; Schaal and Lee, 1992c). In material from the authors' laboratories, the isolation rates of *A. naeslundii* and *A. viscosus* in infections suspected of being of an actinomycotic nature amounted to 7.6% and 4.1%, respectively (Schaal and Lee, 1992c). However, in a comparative study of such infections in which the ways of obtaining specimens (intraoral incision/puncture vs. extraoral incision/puncture) were compared, it could be demonstrated that the isolation of these *Actinomyces* species is often related to contamination of the specimen with oral secretions (Schaal and Pulverer, 1984c). Therefore, involvement of these organisms in cervicofacial or pulmonary infections remains to be definitely clarified. On the other hand, *A. naeslundii* has been reported convincingly as the causative agent of gallbladder infections (Freland et al., 1987), pelvic infections (Bonnez et al., 1985), a precostal abscess resulting from mediastinal actinomycosis (Chapoy et al., 1984), and a disseminating infection in a mentally retarded child (Dobson and Edwards, 1987). Furthermore, a case was observed of recurring empyema of the knee joint in which *A. naeslundii* was isolated on several occasions as the only pathogen (Schaal and Pulverer, 1984c), and similar infections were reported for a total knee arthroplasty (Ruhe et al., 2001) and a hip prosthesis (Wüst et al., 2000).

Similarly, *A. viscosus* has been isolated from thoracic infections, chest wall abscesses, an abscess following a dog bite (del Carmen Pinilla

and Ciniglio, 1983; Spiegel and Telford, 1984b), and even from blood samples of patients with endocarditis (Mardis and Many, 2001).

Reports on *Actinomyces odontolyticus* as a human pathogen are still scarce although their number has apparently increased recently. In material from the authors' laboratories, the relative incidence of this species was 1.8% of all actinomycete isolates encountered (Schaal and Lee, 1992c). Both the clinical picture and course of infections due to *A. odontolyticus* are usually noncharacteristic, so whether such infections should be termed "actinomycosis" is doubtful (Peloux et al., 1983; Kjaaborg et al., 1985). Nevertheless, various types of inflammatory processes have been attributed to *A. odontolyticus* as the causative agent: These were an ulcer of the oral mucosa (Alamillos-Granados et al., 2000), peritonsillar abscesses (Civen et al., 1993) from which *A. odontolyticus* was isolated in 23% of the specimens examined (Jousimies-Somer et al., 1993), enterocutaneous fistulation (Kjaaborg et al., 1985; K. P. Schaal, unpublished observation), multiple liver abscesses (Ruutu et al., 1982), thoracic infections including lung infections with or without extension to the pleural space, mediastinum, or pericardium (Baron et al., 1979; Hooi et al., 1992; Ibanez-Nolla et al., 1993; Verrot et al., 1993; Dontfraid and Ramphal, 1994; Bassiri et al., 1996; Perez-Castrillon et al., 1997; Litwin et al., 1999), brain abscess (Simpson et al., 1996), and even septicemia (in association with *Fusobacterium necrophorum*; Raoult et al., 1982).

Actinomyces meyeri has been isolated frequently from brain abscesses and pleural fluid (Cato et al., 1984) and less often from cervicofacial abscesses (Pordy, 1988), lung and breast abscesses (Rose et al., 1982; Rippon and Kathuria, 1984; Ferrier et al., 1986; Allen, 1987), pneumonitis (Allworth et al., 1986), and abscesses with or without osteomyelitis of hip, leg and foot (Cato et al., 1984; Ferrier et al., 1986; Pang and Abdalla, 1987; Machet et al., 1993) as well as from spleen, liver or perianal infections and infected bite wounds (Cato et al., 1984; Garcia-Corbeira and Esteban-Moreno, 1994; Garduno et al., 2000; Gayraud et al., 2000; Harsch et al., 2001). Furthermore, *A. meyeri* infections show a striking tendency to disseminate so that various organs including heart valves or the brain may become involved (Lentino et al., 1985; Ferrier et al., 1986; Marty and Wüst, 1989; Kuijper et al., 1992; Apotheloz and Regamey, 1996; Chaumentin et al., 1997; Van Mook et al., 1997; Huang et al., 1998). Even an infection of the umbilical cord has been described (Wright et al., 1994).

Both *Actinomyces radingae* and *A. turicensis* were primarily isolated from various polymicrobial infections (Wüst et al., 1995) but occasion-

ally also as pure cultures (Clarridge and Zhang, 2002). In recent studies by Sabbe et al. (1999) and Clarridge and Zhang (2002), *A. radingae* was found in patients with skin-related and soft tissue conditions. The main sources of *A. turicensis* were genital infections, followed by skin (Lepe et al., 1998) and urinary tract infections (Clarridge and Zhang, 2002). Involvement of the appendix, gallbladder, ear, nose and throat was also noted, as was bacteremia.

The two subspecies of *Actinomyces neuii* were isolated mainly from abscesses in association with mixed anaerobic flora and from human blood cultures (Funke et al., 1994) but not from typical actinomycotic lesions. Further conditions in which this coryneform species may be etiologically involved are infected atheromas (Funke and Von Graevenitz, 1995a), infected mammary prostheses (Brunner et al., 2000), chronic osteomyelitis (Van Bosterhaut et al., 2002), postoperative endophthalmitis (Garelick et al., 2002), and neonatal sepsis following chorioamnionitis (Mann et al., 2002).

Actinomyces europaeus was found in abscesses of various locations (breast abscess, suprapubic abscess, perianal abscess, and labial abscess) but also in femur tissue, secretions from a decubital ulcer, and an atheroma cyst (Funke et al., 1997a; Clarridge and Zhang, 2002). It was also detected in patients suffering from urinary tract infections (Sabbe et al., 1999).

The few isolates of *Actinomyces graevenitzii* encountered so far were cultured from bronchial secretions and osteitis material (Pascual Ramos et al., 1997a), *A. radidentis* was derived from infected root canals of human teeth (Collins et al., 2000b; Kalfas et al., 2001), *A. urogenitalis* was detected in urine, vaginal or urethral secretions (Nikolaitchouk et al., 2000) and scrapings from a penis ulcer (K. P. Schaal, unpublished observation), and the three presently described strains of *A. funkei* were from a case of endocarditis, a human sternum wound, and an abdominal incision (Lawson et al., 2001b; Westling et al., 2002). The eight strains of *A. cardiffensis* described so far originated from intrauterine contraceptive devices without reported signs of inflammation (three strains), from multiple abscesses in a patient four weeks after mastoidectomy together with a complex concomitant bacterial flora, from pleural fluid of a patient suffering from shortness of breath and wheezing, from pus of an actinomycotic jaw abscess, from a pericolic abscess, and from a right antral washout of a patient with sinusitis (Hall et al., 2002). The single isolates described as *A. nasicola* (Hall et al., 2003b), *A. oricola* (Hall et al., 2003d), and *A. hongkongensis* (Woo et al., 2003) originated from pus from the nasal antrum, a dental abscess, and a patient with suspected pelvic actinomycosis, respectively.

Actinomyces georgiae is the only human *Actinomyces* species described so far that has not been associated with human disease (Johnson et al., 1990).

CARIES, PERIODONTITIS AND GINGIVITIS From an economical and social point of view, caries, periodontal disease (periodontitis), and gingivitis are probably the most common and most important impairments in which *Actinomyces* species are etiologically involved. Although these conditions are complex in their pathogenesis, certain bacteria have been incriminated as contributors to their development (Slack and Gerencser, 1975; Newman, 1984; Page, 1986). In recent years, innumerable reports have been published which tried to elucidate the role these bacteria (including the fermentative actinomycetes) may play in the etiology of caries, periodontal disease, and gingivitis. This overwhelming quantity of information cannot be discussed in any detail in this chapter. Thus, only a brief summary of the major findings will be given.

Because of the adherence and coaggregation mechanisms which *Actinomyces* species manifest (see the subsection on Ecology in this Chapter), these organisms play an important role in the formation of dental plaque (see Slack and Gerencser, 1975), which is thought to be a prerequisite for the development of caries, periodontal disease, and gingivitis (Winford and Haberman, 1966; Socransky, 1970; Jordan and Hammond, 1972; Jordan and Sumney, 1973), although it must not in itself be considered pathological. Filamentous bacteria were found to contribute markedly to the volume of plaque and to supply an enormous additional surface area for the attachment of other bacteria (Boyd and Williams, 1971; Boue et al., 1987; Fure et al., 1987).

One of these filamentous bacteria, *Corynebacterium matruchotii*, was shown to form intracellular deposits of calcium phosphate that are indistinguishable from bone and tooth apatite (Ennever, 1960; Takazoe, 1961; Ennever et al., 1971; Ennever et al., 1978; Boyan-Salyers et al., 1978). This interesting ability contributes to the calcification of plaque, which leads to increased gingival irritation and subsequent inflammation (Slack and Gerencser, 1975).

Because of these and other striking features, fermentative actinomycetes including *Actinomyces* species have attracted the attention of many workers who are interested in the pathophysiology, cure, and prevention of oral and dental diseases and impairments (Winford and Haberman, 1966; Socransky, 1970; Jordan and Hammond, 1972; Jordan and Sumney, 1973; Moore et al., 1982; Loesche et al., 1983; Hoshino, 1985; Björndal and Larsen, 2000; Sunde et al., 2000;

Ximenez-Fyvie et al., 2000a; Ximenez-Fyvie et al., 2000b), although many other oral microorganisms, especially the cariogenic streptococci, have an even more important etiological role to play.

The capacity of fermentative saccharolytic bacteria including the actinomycetes to produce various organic acids thereby lowering the pH values in dental plaque has been mentioned in the subsection on Physiology in this Chapter; pH values of 5 or lower initiate the process of demineralization of the enamel, which is the first step in the development of caries and which can also be demonstrated *in vitro* (Clarkson et al., 1987; Kaufman et al., 1988). The carbohydrate sources for this acid production may be either of exogenous origin from the host's diet or of endogenous origin from the synthetic action of plaque bacteria (e.g., glycogen, levan, and dextran; Zero et al., 1986). In contrast, ureolytic activities of microbes of the dental plaque may be responsible for alkali production that causes fluoridated apatite to precipitate in the matrix (Gallagher et al., 1984).

Many additional factors that might contribute to the pathogenic effects of actinomycetes have been detected. Oral microorganisms including actinomycetes were found to possess fibrinolytic and fibrinolytic activities (Wikstrom et al., 1983). *Actinomyces israelii* and *A. odontolyticus* elaborate factors that adversely affect fibroblasts (Duguid, 1985). Specific surface components of *A. viscosus* exhibit mitogenicity for splenocytes including the B-cell subpopulation (Engel et al., 1984; Baker, 1985; Halfpap et al., 1985) and induce *in vitro* proliferation of T lymphocytes (Burckhardt, 1978). In addition, similar components were found to activate the alternate complement pathway (Baker and Billy, 1983a). The same species exerts chemotactic effects, is able to mark fibroblasts for immune-mediated damage, and possesses amphipathic antigens (Engel et al., 1976; Engel et al., 1978; Wicken et al., 1978). Furthermore, the type 2 fimbrial lectin of *A. viscosus* was demonstrated to stimulate superoxide and lactoferrin release from polymorphonuclear leukocytes, and it also mediates phagocytosis and subsequent killing of the bacteria (Taichman et al., 1978; Sandberg et al., 1986). On the other hand, sialic acid localized on the surface of *A. viscosus* has been implicated in the inhibition of the alternate complement pathway activation and subsequent opsonophagocytosis (Jones et al., 1986).

In the pulps and periapical tissue of diseased teeth, actinomycetes were identified histologically (Levine et al. 1985), immunocytochemically (Happonen et al., 1985), and by molecular methods (Sunde et al., 2000). *Actinomyces radicidentis* was exclusively found in infected root canals,

especially after conventional root canal treatment (Kalfas et al., 2001). In children with nursing caries, *A. israelii* was found to constitute 18.2% of the flora of the carious lesions, but this species was not identified in corresponding plaque samples in which *A. naeslundii* and *A. odontolyticus* predominated (Marchant et al., 2001). Penetrating *A. viscosus* and *A. naeslundii* cells and antigens were found to be always associated with antibodies and frequently also with complement (Pekovic et al., 1987). The involvement of plasma cells and T cells was also demonstrated and cytotoxic and Arthus type immunopathological reactions occurred (Pekovic and Fillery, 1984). In patients with hereditary fructose intolerance, the common gingival bleeding was related to the more frequent occurrence of *Actinomyces odontolyticus*, *Veillonella parvula* and *Campylobacter rectus* (Saxen et al., 1989).

Indirect evidence for the pathogenic potential of the microflora of dental plaque has been obtained from studies in which various antimicrobial substances were used to prevent or reduce plaque formation. Disinfectants in mouthrinse formulations such as bisguanides, phenols, quaternary ammonium compounds, oxygenating compounds, plant extracts, and fluorides, as well as antibiotics such as tetracyclines and antimicrobial combinations, were all found to inhibit growth and polymer production of oral microbes *in vitro* and *in vivo*, thereby reducing the intensity of plaque formation (Baker et al., 1983b; Slee and O'Connor, 1983; Meiers and Schachtele, 1984; Pallanza et al., 1984; Wegman et al., 1984; Gaffar et al., 1985; Hall et al., 1987; Schaecken and De Haan, 1989; Modesto et al., 2000; Phan et al., 2000; Feres et al., 2001). Furthermore, it could be demonstrated that the topical and, in case of the antibiotics, systemic application of the substances mentioned above was able to inhibit the development of caries, periodontal disease, and gingivitis (Paolino and Kashket, 1985; Gusberti et al., 1988; Walker, 1988).

TREATMENT OF ACTINOMYCES INFECTIONS AND ANTIMICROBIAL SUSCEPTIBILITY OF ACTINOMYCES SPECIES

In addition to typical actinomycoses, the vast majority of the other diseases that may be caused by *Actinomyces* species also have a polymicrobial etiology. Therefore, successful treatment of these conditions depends not only on the type of disease and its localization, but also, often more importantly, on the composition of the synergistic concomitant flora. Caries and periodontitis can usually be treated successfully using the various local measures of conservative and operative dentistry, although administration of suitable antibiotics may facilitate therapy of

periodontitis and especially of gingivitis. Lacrimal canaliculitis and other, noninvasive, eye infections usually also respond immediately to local measures such as removal of lacrimal concretions and the local application of β -lactam antibiotics or other drugs effective against the causal microflora. β -Lactam antibiotics are also the drugs of choice for treating monoinfections due to one of the recently described *Actinomyces* species.

In contrast, typical actinomycotic lesions have been known for many years to be notoriously difficult to treat. Penicillin G, which had been considered the drug of choice for many years (Slack and Gerencser, 1975; Lerner, 1988) because of its high *in vitro* activity against the pathogenic actinomycetes, is often not able to completely cure these infections even when the drug is administered in high doses for weeks or even months (Akgun et al., 1985; McNeil and Schaal, 1998). According to statistics based upon more than 4000 cases, failure of penicillin G treatment (including relapses) can be estimated at about 15–20% (Schaal and Pape, 1980). These treatment failures and relapses within a period of weeks or months after discontinuing antibiotic therapy can be attributed to the presence of penicillin-resistant concomitant organisms, especially *Actinobacillus actinomycetemcomitans* and *Bacteroides* species or other β -lactamase-producing organisms. In cases in which the penicillin resistance of the concomitant bacteria (such as in *Actinobacillus actinomycetemcomitans*) is not related to β -lactamase production, administration of penicillin G often results in elimination of the actinomycetes, but the inflammatory process continues because of the pathogenic potential of the remaining penicillin-resistant members of the synergistic flora. When β -lactamase producing organisms are present, they usually protect the actinomycetes from the action of the drug. On the other hand, clindamycin administration (Martin, 1985; Nielsen and Novak, 1987; Schaal, 1996; Schaal, 1998) may result in the selection of *Actinobacillus actinomycetemcomitans* without cessation of the clinical symptoms.

Alternative therapeutic measures for treating human actinomycoses, besides their good efficacy against fermentative actinomycetes, should also be sufficiently active against *Actinobacillus actinomycetemcomitans* and the common *Bacteroides*, *Prevotella* and *Porphyromonas* species (Schaal and Pape, 1980; Niederau et al., 1982; McNeil and Schaal, 1998). The former is achieved by using aminopenicillins instead of penicillin G (Schaal and Pape, 1980; Martin, 1984), the latter by combining an aminopenicillin with either a β -lactamase inhibitor or an agent effective against Gram-negative anaerobes (Niederau et al., 1982; Nord and Kager, 1983;

Narikawa, 1986; Collignon et al., 1988; Schaal, 1996; Schaal, 1998). Thus, in the past 20 years, by far the best results have been observed from combinations of ampicillin or amoxicillin with clavulanic acid or with metronidazole or clindamycin. Since amoxicillin + clavulanic acid in high doses was introduced as the treatment of choice, the authors have not observed any further treatment failure, even in chronic cases resistant to treatment with penicillin G and other antibiotics for months or years. Further alternatives that may be required if the patient is allergic to aminopenicillins are cefoxitin (Schaal et al., 1979b), imipenem (Dubreuil et al., 1987; McNeil and Schaal, 1998), or minocycline (Schaal, 1979a; Martin, 1985).

Because of the comparatively slow and anaerobic growth of *Actinomyces* species, special conditions are required for antimicrobial susceptibility testing of these organisms (Schaal and Pape, 1980). Mueller-Hinton broth or agar (commonly used for susceptibility testing of bacterial pathogens) does not promote the growth of fermentative actinomycetes adequately so that minimal inhibitory concentrations (MICs) found with these media are usually by far too favorable. The same is true for partially defined media such as Iso Sensitest Agar (Oxoid). However, reproducible results that correlate well with clinical efficacy can be obtained when DST agar (Oxoid, CM 261) is employed (Schaal and Pape, 1980).

The slow and often filamentous growth of fermentative actinomycetes also does not allow sufficient standardization of the agar dilution and broth dilution tests, respectively. Thus, essentially the only technique found to give reproducible and clinically suitable results of susceptibility testing of the bacteria is the agar dilution test using DST agar as test medium and microscopic assessment of results after only 24 h to a maximum of 48 h of incubation (Schaal and Pape, 1980). Using this procedure, it has been shown that nearly all of the penicillins, cephalosporins, and carbapenems currently in use are highly active against the classical *Actinomyces* species, aminopenicillins being particularly effective (Schaal et al., 1979b; Schaal and Pape, 1980; Niederau et al., 1982). The same is true for lincosamides, macrolides, rifamycins and vancomycin. In contrast, no or only very weak activity was observed for aminoglycosides, imidazoles and colistin.

Animal Diseases Caused by *Actinomyces* Species

ANIMAL ACTINOMYCOSIS Since the first description of bovine actinomycosis (Bollinger, 1877), cattle have been known to suffer frequently from this infection. Bovine actinomycosis, which is also called "lumpy jaw," is a chronic suppurative

Fig. 27. Bovine mandibula showing a sponge-like osseous deformation caused by actinomycotic simultaneous osteoclastic and osteoblastic processes.

disease that, as in humans, tends to form multiple abscesses and draining sinus tracts. In contrast to human cases, however, bones are usually involved, mainly the mandible and occasionally the maxilla. The affected bones are slowly deformed by a destructive and, at the same time, proliferative osteitis (Fig. 27) (Slack and Gerencser, 1975). Primary lung infections in cattle have been reported (Biever et al., 1969).

The source of infection in cattle is not definitely established, but in analogy to humans, has been assumed to be endogenous although the principal etiological agent of bovine actinomycosis, *Actinomyces bovis* (Bollinger, 1877; Slack and Gerencser, 1975), has not been demonstrated in the oral cavity of healthy cattle even when modern isolation and identification methods were applied (Dent and Williams, 1984b). Bovine infections due to *A. israelii* were also reported (King and Meyer, 1957; Cummins and Harris, 1959; Pine et al., 1960) but remain to be confirmed using modern reliable identification methods. The same is true for the isolation of *A. israelii* from different organs and muscles of dead, disabled, diseased, dying and normal carcasses of sheep (Goda et al., 1986) and for the role of *A. viscosus* as an etiological agent of abortion in cattle (Okewole et al., 1989).

Clinically similar, but not identical diseases in which fermentative actinomycetes were incriminated as causative agents were reported from swine (Magnusson, 1928; Franke, 1973). These infections appear to involve the udder, lungs or other internal organs more frequently than the neck or bones. "*Actinomyces suis*" (Grässer, 1957; Franke, 1973), *A. israelii* (Magnusson, 1928), and *A. viscosus* (Georg et al., 1972) were reported from these infections. "*Actinomyces suis*" Franke 1973 was listed as species *incertae sedis* in *Bergey's Manual of Systematic Bacteriology* (Schaal, 1986a), but an immunohistochemical study of Murakami et al. (1998) appears to indicate that this species might be separable

from other actinomycetes found in swine. One of these other hog species that had been isolated from purulent vaginal discharge, resembling "*A. suis*" phenotypically, was recently described as *Actinomyces hyovaginalis* (Collins et al., 1993). A further new species from pig mastitis was named "*Actinomyces suimastitidis*" (Hoyles et al., 2001). To make the situation even more complicated, an organism formerly known as "*Eubacterium suis*" (Wegienek and Reddy, 1982b) was first transferred to the genus *Actinomyces* as *Actinomyces suis* (Ludwig et al., 1992) and then to the new genus *Actinobaculum* as *Actinobaculum suis* (Lawson et al., 1997). The latter organism has been isolated from pigs with cystitis and pyelonephritis as well as pregnant sows with metritis (Soltys and Spratling, 1957; Soltys, 1961), so that it remains to be clarified which of these species are the most important swine pathogens.

Comparatively frequently, *Actinomyces* infections were also reported from dogs and cats (McGaughey et al., 1951; Georg et al., 1972; Davenport et al., 1974; Davenport et al., 1975; Moens and Verstraeten, 1980; Hardie and Barsanti, 1982). These included infections of the soft tissue of the jaw as well as thoracic and abdominal manifestations. Tail, scrotum, lymph nodes, epidural space, and vertebrae or other bones may also be affected (Bestetti et al., 1977; Johnson et al., 1984; Murakami et al., 1997). *Actinomyces viscosus* was found to cause most of the infections encountered in dogs or cats (Georg et al., 1972; Davenport et al., 1974; Davenport et al., 1975; Bestetti et al., 1977; Moens and Verstraeten, 1980; Hardie and Barsanti, 1982; Johnson et al., 1984; Murakami et al., 1997). In one dog with a subvertebral mass and quadriplegia (Edwards et al., 1988), *Actinomyces odontolyticus* was identified as the causative agent.

Further *Actinomyces* species that are or may be specific pathogens of dogs and cats have been described (Buchanan et al., 1984b; Pascual et al., 1999; Hoyles et al., 2000; Hoyles et al., 2001). *Actinomyces hordeovulneris* (Buchanan et al., 1984b) was first isolated from pleuritis, peritonitis, visceral abscesses, septic arthritis, and recurrent localized infections of dogs in California and was found to be frequently associated with injuries caused by awns of the grass genus *Hordeum*. These awns, which easily penetrate skin or mucous membranes, are propelled forward through the tissue with any adjacent muscle contraction, leaving trails of inflammation and necrosis (Brennan and Ihrke, 1983). Infections due to *A. hordeovulneris* in dogs have also been reported in Hungary (Pelle et al., 2000) and were occasionally seen in Germany (K. P. Schaal, unpublished observation). The ability of this pathogen to produce L-phase variants spontaneously with coincident calcium deposition

(Buchanan and Scott, 1984a) was believed to be related to sulfur granule formation *in vivo*. As *A. hordeovulneris* could be recovered from the gingival margin of cats (Love et al., 1990), it appears sensible to assume that the organism is introduced from the oral cavity or intestinal tract when mucous membranes are penetrated by the awn or the animal licks or bites a wound. In addition or alternatively, the pathogen may have spread hematogenously to the necrotic focus resulting from an awn injury.

OTHER ANIMAL INFECTIONS *Actinomyces bowdenii* (Pascual et al., 1999) is another new species that was isolated from canine and feline clinical specimens, in particular from an abscess under the mandible of a dog, from feline pleural fluid, from a canine neck abscess, and from a canine pyogranuloma. All of the isolates were found to be associated with aerobically or anaerobically growing concomitant organisms such as *Pasteurella multocida* or *Bacteroides*, *Prevotella* or *Fusobacterium* species.

Actinomyces canis (Hoyles et al., 2000) was isolated in mixed culture with other bacteria from the vagina and pus specimens of dogs. The two strains identified so far as *Actinomyces catuli* (Hoyles et al., 2001) were of similar origin, as was the single strain of *Actinomyces coleocanis* (Hoyles et al., 2002), which was detected in vaginal secretions of a cocker spaniel dog together with "*Corynebacterium genitalium*."

Actinomycosis-like lesions have been reported from sheep, goats, horses, deer, moose, antelope, mountain sheep, gazelles and even an arctic fox (Slack and Gerencser, 1975; Raju et al., 1986; Snyder et al., 1987). However, little detailed information on the *Actinomyces* species involved is available. In one case of pyogenic granulomas found in the abdomen of a mandrill, *A. israelii* was identified as the etiologic agent by immunofluorescence (Altman and Small, 1973). *Actinomyces marimammalium* (Hoyles et al., 2001) was isolated from two dead seals and a dead porpoise, but its pathogenic potential has not been determined yet. *Actinomyces vaccimaxillae* (Hall et al., 2003) was cultured from pus of a jaw lesion in an adult cow, thus resembling in this respect *A. bovis*. Finally, *A. viscosus*, serovar 1, and possibly other *Actinomyces* species have been isolated from dental plaque of hamsters and beagle dogs with naturally occurring periodontitis (Howell, 1963a; Jordan and Keyes, 1964; Jordan and Keyes, 1965a; Syed et al., 1981).

EXPERIMENTAL ANIMAL INFECTIONS Various domestic and laboratory animals including horses, cattle, sheep, goats, pigs, dogs, rabbits, guinea pigs, rats, hamsters and mice have been used to produce experimental infections with *Actinomyces* species (Slack and Gerencser,

1975). After intraperitoneal, intravenous or subcutaneous injection, *Actinomyces bovis*, *A. israelii*, *A. naeslundii*, *A. odontolyticus* and *A. viscosus* were all found to cause abscess formation; some of these abscesses resembled naturally occurring actinomycotic lesions (Schaal, 1986a). However, progressive infections rarely developed from these abscesses, and the infected animals usually survived. Furthermore, detailed histopathological examinations showed that the actinomycotic lesions produced by *A. israelii* in mice differed considerably from those following challenge with *A. viscosus* or *A. naeslundii* (Behbehani et al., 1983a). These and other findings indicate that the virulence of *Actinomyces* species apparently varies both between species and between individual strains, and the susceptibility of the test animals may also vary considerably (Wolff and Israel, 1891; Pine et al., 1960; Coleman and Georg, 1969; Georg and Coleman, 1970; Georg et al., 1972; Beaman et al., 1979). In addition, it has been demonstrated that the simultaneous challenge with *A. israelii* and *Eikenella corrodens* decreased the minimal infecting dose of *A. israelii* considerably, stressing the role of mixed infections in the naturally occurring disease (Jordan et al., 1984). Similar results were obtained when *A. israelii* cells were packed in alginate gel particles, which led to the formation of structures comparable with sulfur granules (Sumita et al., 1998). Using an ischemic mouse thigh model for evaluation of pathogenicity, Chatterjee and Chakraborti (1989) found that *A. naeslundii*, under these experimental conditions, exhibited an especially high degree of virulence, causing death in all test animals within 24 h.

The only animal *Actinomyces* species that appear to be nonpathogenic in general are *Actinomyces denticolens*, *A. howellii* and *A. slackii*, although detailed pathogenicity studies have not been performed with these organisms.

Numerous animal experiments were performed on the ability of actinomycetes to colonize teeth (De Jong et al., 1983; Crawford and Clark, 1986) and on their role in the development of caries and periodontitis. After oral inoculation, *A. viscosus* and *A. naeslundii* were both shown to produce periodontal disease with alveolar bone loss and root surface caries in hamsters (Jordan and Keyes, 1964; Hernandez, 1985; Kametaka et al., 1989) as well as in conventional and gnotobiotic rats (Jordan et al., 1965b; Socransky et al., 1970; Llory et al., 1971; Brecher et al., 1978; Crawford et al., 1978; Brecher and Van Houte, 1979; Burckhardt et al., 1981; Shakespeare et al., 1985; Firestone et al., 1987; Firestone et al., 1988). Similar observations were made for *Actinomyces israelii* orally implanted into gnotobiotic rats, which produced extensive

plaque formation accompanied by root surface caries and bacterial invasion of the pulp (Behbehani et al., 1983b).

The factors of pathogenicity and virulence, which enable *Actinomyces* species to invade the tissue and to cause necrosis and abscess formation, remain to be elucidated in detail. Some of the virulence factors that are involved in the development of caries, gingivitis and periodontal disease have been mentioned in the sections on the respective human diseases.

The Genus *Actinobaculum*

The genus *Actinobaculum* was introduced by Lawson et al. (1997) to accommodate bacterial strains that had previously been assigned to various other genera and that were named "*Actinobaculum suis*," together with recent *Actinomyces*-like isolates from human clinical specimens for which the designation "*A. schaalii*" was proposed. The taxonomic and nomenclatural history of *A. suis* is unusually varied: In 1957, Soltys and Spratling proposed the name "*Corynebacterium suis*" for an organism which was associated with cases of cystitis and pyelonephritis in pigs. This generic assignment was apparently based almost exclusively on the diphtheroid morphology of the organism, a common practice at that time. Neither "*Corynebacterium suis*" Soltys and Spratling nor "*Corynebacterium suis*" Hauduroy et al. (1937) was included in the Approved Lists of Bacterial Names (Skerman et al., 1980), and therefore neither has nomenclatural standing.

In a taxonomic study of "*Corynebacterium suis*," Wegienek and Reddy (1982b) found that "*Corynebacterium suis*" strain Soltys 50052 is anaerobic, has rhamnose and lysine as major cell components, and produces acetate, formate and ethanol as major end products of carbohydrate metabolism. In contrast, representatives of the genus *Corynebacterium* are aerobic or facultatively anaerobic organisms characterized by cell walls containing arabinose and galactose as the major sugar components and *meso*-diaminopimelic acid as the major diamino acid. Furthermore, they produce major amounts of acetate, propionate and formate and variable amounts of other acids as products of carbohydrate metabolism (Reddy and Kao, 1978). Thus, Wegienek and Reddy (1982b) concluded that this strain did not belong to the genus *Corynebacterium* and they proposed, despite differences in cell wall composition and DNA base ratios, that the organism should be included in the genus *Eubacterium*. Their proposal was based on a rather limited number of characteristics such as anaerobiosis, morphology, as well as absence

of propionate, lactate and succinate among the end products of carbohydrate metabolism.

Comparative sequence analysis of the 16S rRNA gene of "*Eubacterium suis*" showed that this organism is a close relative (93.8% sequence similarity) of "*Actinomyces pyogenes*" (Ludwig et al., 1992). These two organisms share a common cell wall composition (lysine is the diamino acid; rhamnose and traces of mannose are the cell wall sugars), they both contain type *c* cytochromes, and they have similar DNA G+C contents (55 and 56–58 mol%, respectively; Soltys and Spratling, 1957; Schaal and Pulverer, 1981b; Wegienek and Reddy, 1982b; Schaal, 1986a). Differences in the biochemical characteristics of "*Eubacterium suis*" Soltys and Spratling and the species *incertae sedis* "*Actinomyces suis*" Franke 1973 indicate that these two organisms are not identical. Since no type strain of "*Actinomyces suis*" Franke is extant, Ludwig et al. (1992) proposed that "*Eubacterium suis*" should be transferred to the genus *Actinomyces* as "*Actinomyces suis*." The reclassification in the newly created genus *Actinobaculum* as *Actinobaculum suis* by Lawson et al. (1997) was then a consequence of the results of a comparative 16S rRNA gene sequence analysis.

Taxonomy

The genus *Actinobaculum* currently comprises four validly described species (Table 1). The taxonomic history of *Actinobaculum suis* has been discussed above. The species *Actinobaculum schaalii* was proposed by Lawson et al. (1997) for human bacterial isolates that originated from urine or blood. Two other isolates from human urine were described as *Actinobaculum urinale* (Hall et al., 2003c) and *Actinobaculum massiliae* (Greub and Raoult, 2002), respectively.

CHEMOTAXONOMIC PROPERTIES Apart from phylogenetic evidence, the inclusion of these organisms in the genus *Actinobaculum* has not been substantiated by other taxonomically relevant properties such as chemotaxonomic features which usually provide useful additional criteria for the delineation of genera. Thus, despite differences in the cell wall murein types of *Actinobaculum suis* (L-Lys-L-Ala-L-Lys-D-Glu) and *Actinobaculum schaalii* (L-Lys-L-Lys-D-Glu), the assignment of both species to the same genus was considered to be justified because of the close affinity suggested by their 16S rRNA gene sequence similarity (approximately 94%) and a statistically significant phylogenetic association with one another (bootstrap value of 100%).

In an extensive chemotaxonomic study of *Actinobaculum suis*, the type species of the genus *Actinobaculum*, this species was found to be

Table 13. Comparative chemotaxonomic characteristics of members of three validly described genera of the family Actinomycetaceae.

Organisms	Chemotaxonomic characteristics				
	Wall sugars	Acyl type	Phospholipid type	Menaquinones	Fatty acids
<i>Actinomyces bovis</i>	Glucose + mannose + rhamnose + 6-deoxytalose	Acetyl	PIII DPG, PC, PI, PIM	MK-8 + MK-9 ^a + MK-10 + <i>methyl</i> -MK-10	S, U
<i>Actinobaculum suis</i>	Galactose + mannose + rhamnose	Acetyl	PI DPG, PG, PI, PIM	MK-10(H ₄) ^a	S, U
<i>Arcanobacterium haemolyticum</i>	Rhamnose + glucose	Acetyl	PIII DPG, PG, PC, PI, PIM	MK-8(H ₄) + MK-9(H ₄) ^a	S, U

^aMajor component.

characterized by a cell-wall sugar pattern composed of galactose, mannose and rhamnose and by a Phospholipid Type PI *sensu* Lechevalier et al. (1977) in that it contains the phospholipids diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol dimannosides (Table 13). Its respiratory quinones consist of tetrahydrogenated menaquinones with ten isoprene units (MK-10[H₄]) as the only isoprenoid quinones; the fatty acid profile comprises straight-chain saturated and monounsaturated fatty acids; its muramic acid residue is N-acetylated (Table 13). However, chemotaxonomic investigations on cell wall components of the type strain of *Actinobaculum schaalii* showed that the latter species possesses a completely different chemotaxonomic pattern (A. F. Yassin, unpublished observation; data not shown) as compared to that of *Actinobaculum suis*. Thus, these findings revealed considerable chemotaxonomic heterogeneity within the genus *Actinobaculum*, so that the genus *Actinobaculum* as currently defined apparently needs taxonomic revision.

Detailed long-chain cellular fatty acid profiles were given for *A. schaalii*, *A. massiliae* and *A. urinale* and were found to consist of straight-chain saturated and monounsaturated fatty acids.

The DNA base composition of members of the genus was reported to be 55–57 mol% G+C.

MORPHOLOGICAL CHARACTERISTICS Additional characteristics that were used to circumscribe the genus *Actinobaculum* consist of a rather limited number of common features. Among them, the morphology of members of the genus has been summarized as follows (Fig. 28): “On blood agar, cells are straight to slightly curved rods, some of which exhibit branching. Cells are Gram-positive, not acid fast, and non-motile and do not form spores” (Lawson et al., 1997). In the descriptions of *A. suis* and *A. urinale* (Hall et al., 2003), branching cells were not mentioned.

Fig. 28. *Actinobaculum schaalii*; Gram-stained smear from a mature colony (brain heart infusion agar, 14 days at 36 ± 1°C, and Fortner's method).

Fig. 29. *Actinobaculum schaalii*; mature, slightly raised, translucent colony without internal structures; micrograph in transmitted light (brain heart infusion agar, 14 days at 36 ± 1°C, and Fortner's method).

Colonies are predominantly smooth with entire to slightly irregular margins. They are gray to white and, only in the case of *A. urinale*, weakly β-hemolytic (Fig. 29).

PHYSIOLOGICAL PROPERTIES In the description of the genus (Lawson et al., 1997), production of acetate as major end product of glucose and maltose metabolism was given as one of its main diagnostic characteristics. However, *A. urinale* (Hall et al., 2003) appears to differ from this profile in that this species was reported to produce lactic acid as major end product of glucose fermentation, together with minor amounts of acetic acid.

Actinobaculum species were described as anaerobic or facultatively anaerobic, *A. suis* being the only species that appears to prefer anaerobic growth conditions.

As do *Actinomyces* species, members of the genus *Actinobaculum* apparently require complex media for good growth, indicating that their anabolic capacity is limited.

The catabolic activities of *Actinobaculum* species have not been studied comprehensively. The data so far available are summarized in Table 14 together with the respective information for *Arcanobacterium* and *Varibaculum* species. The following physiological properties are common to all four members of the genus: acid production from maltose but not from glucose (which is not fermented by *A. suis*), no esculin and gelatin hydrolysis, lack of arginine dihydrolase, no

catalase production, and no reduction of nitrate. Other physiological features vary from species to species and may therefore be used as differential characteristics.

Habitat and Ecology

Actinobaculum suis was originally isolated from cases of cystitis, pyelonephritis and metritis in pregnant sows (Soltys and Spratling, 1957; Soltys, 1961; Walker and MacLachlan, 1989; Carr and Walton, 1993; Liebhold et al., 1995; Biksi et al., 1997). Although not cultured from healthy sows, the organism was frequently recovered from urine and semen of apparently healthy boars. It was also isolated from the preputium or preputial diverticulum of boars (Sobestiansky et al., 1993; Biksi et al., 1997). The habitat of *A. schaalii* was assumed to be the human genital or urinary tract. This species was isolated from human blood and urine. Similarly, *A. urinale* was cultured under anaerobic conditions from urine of a human female with pyuria, and *A. massiliae*, from urine of an elderly woman with recurrent cystitis.

Isolation and Cultivation

A more detailed study on the nutritional and metabolic features was only performed for *A. suis* (Wegienek and Reddy, 1982a). Excellent growth of this organism was obtained using a peptone-yeast extract-starch (PYS) medium containing trypticase (BD), yeast extract, starch, minerals, cysteine, and sodium carbonate, together with anaerobic conditions. Growth was found to be considerably less when the starch in this medium was replaced by maltose. Deletions of starch or maltose resulted in negligible growth, indicating that a fermentable carbohydrate is required for growth. Furthermore, CO₂ or Na₂CO₃, yeast extract, and trypticase were also required. Yeast extract could be replaced in PYS by a defined mixture of purine and pyrimidine bases, vitamins, and amino acids, but deletion of trypticase resulted in no detectable growth, suggesting a possible peptide requirement of *A. suis*.

The nutritional requirements of the other *Actinobaculum* species are not known in detail. *Actinobaculum schaalii* was successfully cultured on 5% horse blood agar (Columbia base, BD) in a 5% CO₂ atmosphere. *Actinobaculum urinale* grew well on the same medium under anaerobic conditions. *Actinobaculum massiliae* was successfully cultured on Columbia sheep blood agar in a 5% CO₂ atmosphere.

Identification

As the genus *Actinobaculum* is heterogeneous chemotaxonomically as well as physiologically,

there is no single test or a narrow spectrum of physiological markers that would allow the identification of these organisms on the genus or species level. Nevertheless, Gram-positive straight or slightly curved rod-shaped bacteria with or without branching that grow under increased CO₂ tension or anaerobically, produce predominantly acetate or lactate as end products of their carbohydrate metabolism, show acid production from maltose, and are catalase-, nitrate reductase-, esculin hydrolysis-, and gelatinase-negative (Table 14) may well belong to the genus *Actinobaculum*.

Differentiation of the four species of the genus may be achieved by a combination of a number of physiological properties or by molecular methods. A strong urease activity together with acid production from starch and maltose but not from glucose is characteristic of *A. suis* (Table 14). Weak acid production from raffinose, fermentation of trehalose and glycogen, and pyrazinamidase activity may be indicative of *A. massiliae*. *Actinobaculum schaalii* and *A. urinale* may be differentiated from one another and from the two other *Actinobaculum* species by sucrose and xylose fermentation, alanine arylamidase-, alanine phenylalanine proline arylamidase-, α -glucosidase-, leucine arylamidase-, glycine arylamidase-, and tyrosine arylamidase-activities (Table 14).

The methods useful for identifying these bacteria are by and large the same as those described for *Actinomyces* species. However, the evaluation of four commercial identification systems for anaerobes showed (Walker et al., 1990) that two of these systems could identify *A. suis* when colony morphology and Gram reaction were considered in addition. The remaining two systems were of limited or no use for identifying this species.

An indirect immunofluorescence procedure was successfully used both for identifying *A. suis* directly in swabs from the preputial diverticulum of boars (Langfeldt et al., 1990; Sobestiansky et al., 1993) and for detecting antibodies in infected pigs (Wendt and Amsberg, 1995). For the latter test, the authors found a sensitivity of 78.9% when the specificity was 100% for animals actually infected with *A. suis*.

Epidemiology

Essentially nothing is known about the epidemiology of infections due to the recently described human *Actinobaculum* species because only a few cases have been reported.

Actinobaculum suis is an important pathogen in the urogenital tract of pigs. It is a common cause of cystitis and pyelonephritis in breeding sows in Canada, Europe and Australia. Disease

isolates have also been reported from Norway, Denmark, Holland, Hong Kong, Switzerland, Malaysia, Germany, Brazil and the United States (Jones, 1992). However, disease is apparently only produced in sows, whereas boars are only colonized and transmit the organism sexually.

Pathogenicity

Actinobaculum suis is able to produce cystitis, pyelonephritis, metritis and abortion in sows (Soltys and Spratling, 1957; Soltys, 1961; Yamini and Slocombe, 1988). Significant bacteriuria often appears to be the only clinical sign of beginning cystitis (Liebhold et al., 1995). However, more advanced cases frequently show macrohematuria and urinary pH values above 8.0, which are apparently due to the heavy production of ammonia from urea. Primarily, cystitis is the result of colonization of the bladder by *A. suis*, which is facilitated by its ability to adhere to bladder epithelial cells by numerous fimbriae (Larsen et al., 1986). Using scanning electron microscopy, Wendt et al. (1994) were able to demonstrate that the hemorrhagic cystitis, thus induced by *A. suis*, is accompanied by a total loss of superficial cells of the infected bladder mucosa. Nevertheless, these severe alterations appeared to be only possible when previous infections had debilitated the urothelium, thereby supporting infection of the bladder with *A. suis*. This is in accord with the observation that sows can be infected artificially by intrarenal injection of live organisms only when 5% saponin is added to the suspension (Soltys, 1961). Exotoxin activities could be demonstrated in this pathogen (Wegienek and Reddy, 1982b).

The five human isolates of *A. schaalii* described by Lawson et al. (1997) originated from blood (two strains) or urine (three strains). Thus, this organism appears to be a pathogen of the human urinary tract causing cystitis and pyelonephritis possibly associated with bacteraemia or urosepsis. The single isolate of *A. urinale* described so far was also cultured from the urine of a human female patient suffering from pyuria (Hall et al., 2003). Similarly, *A. massiliae* was isolated from the urine of a female patient with catheter-associated cystitis (Greub and Raoult, 2002).

Comprehensive studies on the treatment of *Actinobaculum* infections have not been performed. Only one report (Wendt and Sobestiansky, 1995b) deals with the therapy of urinary tract infections in sows due to *A. suis*. Enrofloxacin and ampicillin were used in this study and proved to be efficient even in cases of hemorrhagic cystitis.

The Genus *Arcanobacterium*

The genus *Arcanobacterium* was described by Collins et al. (1982c) to accommodate bacterial strains originally isolated from infected American soldiers and previously named "*Corynebacterium haemolyticum*" (MacLean et al., 1946). However, the species exhibits little similarity to typical corynebacteria and its placement in the genus *Corynebacterium* was questioned by several workers (Cummins and Harris, 1956; Barksdale et al., 1957; Barksdale, 1970; Jones, 1975; Minnikin et al., 1978; Schofield and Schaal, 1981; Collins et al., 1982b). Furthermore, the relationship of "*C. haemolyticum*" to the species "*C. pyogenes*" (Glage) remained unclear. In a study of cell-wall compositions in some Gram-positive bacteria, Cummins and Harris (1956) noted that the cell-wall compositions of "*C. pyogenes*" and "*C. haemolyticum*" were obviously similar to one another but differed both in sugar and amino acid composition from these of the other corynebacteria (i.e., neither species contains arabinose or galactose, lysine is the diamino acid of the peptidoglycan, and A₂pm is absent). On the other hand, Cummins and Harris (1956) found that rhamnose was present in both organisms, and this, together with the fact that alanine, glutamic acid and lysine were the major amino acid components, led these authors to suggest that the two organisms were related to the streptococci. This view was upheld by Barksdale et al. (1957), who suggested not only that "*C. haemolyticum*" and "*C. pyogenes*" should be reclassified in the genus *Streptococcus*, but also that "*C. haemolyticum*" was a mutant form of "*C. pyogenes*."

In the eighth edition of *Bergey's Manual of Determinative Bacteriology*, both taxa were listed in an addendum to the genus *Corynebacterium* (Cummins et al., 1974), and "*C. haemolyticum*" does not appear in the Approved Lists of Bacterial Names (Skerman et al., 1980).

Later, numerical phenetic (Schofield and Schaal, 1981) and chemical (Collins et al., 1982b) studies showed that "*C. haemolyticum*" and "*C. pyogenes*" are two distinct taxa. The discovery of tetrahydrogenated menaquinones in "*C. pyogenes*" and "*C. haemolyticum*" (Collins et al., 1982b) was not in accord with the inclusion of these taxa in the genus *Streptococcus*. The majority of streptococci completely lack respiratory quinones, although some unsaturated naphthoquinones have been detected in a few group D and group N streptococci (Collins and Jones, 1979a; Collins and Jones, 1979b). In addition, fatty acid data (Collins et al., 1982b) did not support the view of Barksdale et al. (1957) that "*C. haemolyticum*" should be reclassified in the genus *Streptococ-*

cus. “*Corynebacterium haemolyticum*” possesses major amounts of monounsaturated fatty acids of the oleic acid series (synthesized via an aerobic pathway; Collins et al., 1982b). In contrast, members of the genus *Streptococcus* possess monounsaturated fatty acids of the *cis*-vaccenic acid series (synthesized via an anaerobic pathway; Kroppenstedt and Kutzner, 1978). Furthermore, the menaquinone patterns of “*C. pyogenes*” and “*C. haemolyticum*” are also incompatible with the retention of these species in the genus *Corynebacterium*. True corynebacteria generally possess dihydrogenated menaquinones with eight and nine isoprene units (Yamada et al., 1976; Collins et al., 1977). Tetrahydrogenated menaquinones with ten and nine isoprene units have, however, been reported in the genera *Actinomyces* (Collins et al., 1977) and *Propionibacterium* (Schwartz, 1973; Sone, 1974), respectively. Therefore, Reddy et al. (1982) as well as Collins and Jones (1982a) proposed that “*C. pyogenes*” should be reclassified in the genus *Actinomyces*, as “*Actinomyces pyogenes*.” The presence of a peptidoglycan based upon L-lysine in “*C. pyogenes*” supported this view since this amino acid is present in the peptidoglycan of *A. bovis* (Schleifer and Kandler, 1972). “*Corynebacterium pyogenes*” is physiologically similar to *A. bovis*, although it differs from *A. bovis* in being actively proteolytic (Cummins et al., 1974; Slack and Gerencser, 1975). However, the DNA base ratio of “*C. pyogenes*” (58 mol% G+C) is not incompatible with its inclusion in the genus of *A. bovis*, which has 63 mol% G+C (Johnson and Cummins, 1972).

The taxonomic position of “*C. haemolyticum*” remained equivocal. The results of lipid analyses did not support the view of Barksdale et al. (1957) that “*C. haemolyticum*” is a mutant of “*C. pyogenes*.” Phenotypically, “*C. haemolyticum*” is very similar to *A. bovis* and also contains lysine in the cell wall peptidoglycan. The menaquinone composition of “*C. haemolyticum*” is distinct from that of *A. bovis* (Collins et al., 1977) and resembles that of the propionibacteria (Schwartz, 1973; Sone, 1974), but the results of cell wall and fatty acid analyses do not support this latter relationship. On the basis of cell wall and lipid composition, the taxon “*C. haemolyticum*” appeared quite distinct from all other coryneform and actinomycete taxa, thus warranting a new genus (Collins et al., 1982b). Therefore, on the basis of phenetic, peptidoglycan, fatty acid, menaquinone and DNA data (Schleifer and Kandler, 1972; Schofield and Schaal, 1981; Collins et al., 1982b), this taxon was reclassified by Collins et al. (1982c) in the new genus *Arcanobacterium* as *Arcanobacterium haemolyticum*.

Taxonomy

The early description of the genus was mainly based upon morphological characteristics together with some chemotaxonomic information such as peptidoglycan composition, long-chain fatty acid content and respiratory quinone composition (Collins et al., 1982c).

The genus *Arcanobacterium* currently comprises six validly described species, namely *Arcanobacterium bernardiae*, *Arcanobacterium haemolyticum*, *Arcanobacterium hippocoleae*, *Arcanobacterium phocae*, *Arcanobacterium pluranimalium* and *Arcanobacterium pyogenes* (Table 1). This current taxonomic structure has involved the inclusion of species that were transferred to *Arcanobacterium* from other genera. Thus, *Arcanobacterium pyogenes* and *Arcanobacterium bernardiae* were transferred to this genus by Pascual Ramos et al. (1997b) after they had meanwhile been included in the genus *Actinomyces* as “*Actinomyces pyogenes*” and “*Actinomyces bernardiae*,” respectively.

CHEMOTAXONOMIC PROPERTIES The salient chemotaxonomic features of the type strains of *Arcanobacterium haemolyticum*, the type species of the genus, *Arcanobacterium pyogenes*, *Arcanobacterium phocae* and *Arcanobacterium bernardiae* include cell wall chemotype V (Lechevalier and Lechevalier, 1970) with lysine as wall diamino acid, rhamnose as diagnostic whole-cell sugar, a type PIII phospholipid pattern (Lechevalier et al., 1977) with phosphatidylcholine as key diagnostic phospholipid, and tetrahydrogenated menaquinones with eight (MK-8[H₄]) and nine (MK-9[H₄]) isoprene units, the predominant menaquinone being MK-9(H₄); the long-chain fatty acids are straight-chain saturated and monounsaturated (oleic acid series; Table 15).

Other chemotaxonomic properties include lack of mycolic acids, a muramic acid residue of the peptidoglycan that is N-acetylated, and DNA G+C contents between 50 and 58 mol%. This pattern of chemotaxonomic characteristics is unique among the genera of the family Actinomycetaceae (Tables 13 and 15).

MORPHOLOGICAL CHARACTERISTICS When Collins et al. (1982) introduced the genus *Arcanobacterium* for bacteria formerly named “*Corynebacterium haemolyticum*,” the cellular morphology of the genus was described as follows: “On blood agar plates, slender, irregular, bacillary forms predominate during the first 18 h; many cells are arranged at an angle to give V-formations (Fig. 30). As growth proceeds, organisms become granular and segmented so that they resemble small and irregular cocci. Both rods and coccoid

Table 15. Chemotaxonomic characteristics of members of the genus *Arcanobacterium*.

Organisms	Chemotaxonomic characteristics				
	Wall sugars	Acyl type	Phospholipid types	Menaquinones	Fatty acids
<i>Arcanobacterium haemolyticum</i>	Rhamnose + glucose	Acetyl	PIIIDPG, PG, PC, PI, PIM	MK-8(H ₄) + MK-9(H ₄) ^a	S, U
<i>Arcanobacterium bernardiae</i>	Rhamnose + glucose + mannose	Acetyl	PIIIDPG, PG, PC, PI, PIM	MK-8(H ₄) + MK-9(H ₄) ^a	S, U
<i>Arcanobacterium pyogenes</i>	Rhamnose + glucose	Acetyl	PIIIDPG, PG, PC, PI, PIM	MK-8(H ₄) + MK-9(H ₄) ^a	S, U
<i>Arcanobacterium phocae</i>	Rhamnose	Acetyl	PIIIDPG, PG, PC, PI	MK-8(H ₄) + MK-9(H ₄) ^a	S, U, <i>iso</i> , <i>anteiso</i>

Fig. 31. *Arcanobacterium bernardiae*; mature, flat, translucent colony with a small, optically darker center; micrograph in transmitted light (brain heart infusion agar, 14 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

cells are Gram-positive, non-acid fast and non-motile; endospores are not formed."

The morphology of *A. pyogenes* by and large conforms to this description (Reddy et al., 1982; Schaal, 1986b). The same is true for *A. phocae* and *A. bernardiae*, whereas *A. hippocoleae* and *A. pluranimalium* appear to be less coccoid.

Surface colonies of *A. haemolyticum* on blood agar were described to be small after 24 h of incubation at $36 \pm 1^\circ\text{C}$, becoming larger upon extended incubation (Collins and Cummins, 1986). They are circular, discoid, slightly raised, opaque and nonpigmented with a butyrous consistency, and they show β -hemolysis (Fig. 31). Colonies of *A. pyogenes* are very similar, while *A. bernardiae* varies concerning β -hemolysis. *Arcanobacterium phocae* also produces a potent hemolysin, whereas *A. hippocoleae* is weakly β -hemolytic, and *A. pluranimalium* was reported to be α -hemolytic.

PHYSIOLOGICAL PROPERTIES Arcanobacteria are facultatively anaerobic, having a fermentative type of carbohydrate metabolism. Fermentation end products are acetic and lactic acids; the

amount of succinic acid produced may vary from species to species and may even be difficult to detect. Catalase production is negative in *A. bernardiae* and *A. hippocoleae*; it is positive in *A. pluranimalium* and variable in *A. phocae*. Catalase activity in *A. haemolyticum* is usually negative, but some strains may show weak catalase production.

Acid production from various carbohydrates, enzyme activities of *Arcanobacterium* species, and several other physiologic properties are compiled in Table 14. Nearly all members of the genus ferment glucose and maltose, and none produces urease. All of the other physiological characters vary among the *Arcanobacterium* species and may therefore be used for differentiating or identifying them (Table 14).

Habitat and Ecology

Information on the natural habitat of arcanobacteria is scarce, although it has been assumed that these organisms occur as commensals of the mucous membranes of warm-blooded animals,

in particular domestic animals such as cattle, sheep, swine and goats (Reddy et al., 1982; Billington et al., 2002a). Thus, Baele et al. (2001), in a study on the Gram-positive tonsillar and nasal flora of piglets before and after weaning, found that *A. pyogenes* was one of the common colonizers of the tonsils of pigs before and after weaning but not of the nasal conchae. Furthermore, this organism was also isolated from semen of beef breed bulls (Sprecher et al., 1999) without a significant relationship between the cultural results and possible sperm abnormalities. This is in accordance with the findings of Olson et al. (2002) that *A. pyogenes*, as certain *Actinomyces* species, is able to produce biofilms experimentally.

Another interesting finding is that *A. haemolyticum* could be identified as one of the major secondary colonizers of leprosy skin ulcers (Sturm et al., 1996) and may contribute to the inflammatory reaction of these lesions. The vast majority of *Arcanobacterium* isolates originated, however, from various pathological conditions that were thought to be etiologically related to these microbes and that will be discussed in the section on Pathogenicity.

Isolation and Cultivation

For primary isolation and maintenance, organically complex media such as BHI broth (or agar) or trypticase soy broth (or agar) have been recommended and are usually satisfactory. Blood agar, especially Columbia agar with addition of 5% horse, sheep or human blood, in most cases also gives satisfactory results. The blood agar may be layered upon a nutrient or digest agar base (Collins and Cummins, 1986). Good growth of *A. haemolyticum* is more difficult to obtain in liquid media. However, addition of serum may enhance growth considerably. Thus, a suitable liquid medium for this organism consists of brain heart infusion broth supplemented with 5% horse serum (Collins and Cummins, 1986).

Recognition of *A. haemolyticum* in cultures from clinical specimens is often hampered by its delayed β -hemolysis and the presence of additional pathogens (e.g., streptococci) or microbes from the indigenous flora of the affected mucous membranes. Thus, media for selective isolation or improved recognition of this organism were developed: Coman et al. (1996) used a medium containing 5% sheep blood agar and 3.5% NaCl for selective isolation of *A. haemolyticum* from pharyngeal swabs of children. Jurankova and Votava (2001) applied sheep blood agar with a streak of *Staphylococcus aureus* to recognize *A. haemolyticum* on the basis of the reverse CAMP (Christie, Atkins and Munch-Petersen) phenomenon. The medium of Votava et al. (2000) con-

taining Columbia blood agar base and 5% washed sheep erythrocytes sensitized with equi factor (EF) of *Rhodococcus equi* is based upon the same principle.

All of the other *Arcanobacterium* species apparently grow well on Columbia blood agar supplemented with 5% horse or sheep blood and incubated under increased CO₂ tension (~5%) at 36 ± 1°C.

Identification

In view of their unique chemotaxonomic profile, arcanobacteria are most reliably identified to genus level by chemotaxonomic methods. The methodological details of the respective techniques were described in the section on Actinomyces.

Using physiological markers, identification to species level may be achieved by a set of carbohydrate fermentation and enzyme tests that can be selected from Table 14. This set may include acid production from α -methyl-D-glucoside, glycogen, lactose, melezitose, pullulan, sucrose, trehalose, xylitol and xylose, hydrolysis of gelatin and hippurate, the activities of acid phosphatase, α - and β -galactosidases, α -glucosidase, and β -glucuronidase as well as catalase production, acetoin production, and nitrate reduction (Table 14). Characteristically, essentially all of the *Arcanobacterium* species ferment glucose and maltose and are negative for acid production from melibiose and urease activity. Whether *A. haemolyticum* possesses α -mannosidase activity has been a matter of debate: Carlson and Kontiainen (1994a) reported that α -mannosidase activity was a very good character for identifying this species and differentiating it from *A. pyogenes*. However, Von Graevenitz (1994) commented that this enzyme activity could be influenced by various accidental factors, thus making the value of this differential feature questionable. In Table 14, mainly the results of the API system are given as far as enzyme activities are concerned, and with this system, essentially all of the arcanobacteria are α -mannosidase-negative. Additional characters useful for differentiating *A. pyogenes* and *A. haemolyticum* in clinical microbiology laboratories are xylitol and α -methyl-D-glucoside fermentation, acetoin production (Voges-Proskauer test), and α -galactosidase activity (Carlson et al., 1995a).

As with the *Actinomyces* species, various commercial identification systems were used for the primary description of the new *Arcanobacterium* species and for identifying members of the genus (Guerin-Faubleee et al., 1992). However, Brander and Jousimies-Somer (1992) found that the RAPID ANA II system misidentified all *A.*

haemolyticum strains as *A. pyogenes*, although all of the *Actinomyces odontolyticus* and 65% of the *Actinomyces israelii* isolates were correctly identified. On the other hand, the API ZYM profiles were useful for differentiating *A. haemolyticum* and *A. pyogenes*. In contrast, the performance of the Rapid CORYNE system appeared to be considerably better (Gavin et al., 1992), although Ding and Lämmle (1992) and Guerin-Fauble et al. (1992) reported that the "classical" API CORYNE system failed to identify 6 out of 42 *A. pyogenes* and one of five *A. haemolyticum* strains, or only 58 of 103 *A. pyogenes* cultures, respectively. As in *Actinomyces*, 4-methylumbelliferyl-linked substrates may provide additional characters for identifying *A. haemolyticum* (Kämpfer, 1992).

Tentative serological identification of *Actinomyces pyogenes* may be achieved with antisera against group G streptococci using either immunodiffusion or latex agglutination test procedures (Lämmle and Blobel, 1986). Furthermore, Lämmle (1990) reported typing of this organism by its production of and susceptibility to bacteriocin-like inhibitors. A set of morphological and physiological characteristics such as colony morphology, β -hemolysis on horse blood agar, β -glucuronidase activity, and ability to produce acid from sucrose and trehalose was used by Carlson et al. (1994d) to define two biovars of *A. haemolyticum*. A bacteriophage typing system for these organisms has not been developed.

Serological Diagnosis of *Arcanobacterium* Infections

Serology may have some practical importance in diagnosing *Arcanobacterium* infections (unlike *Actinomyces* infections). Votava et al. (2001) used a neutralization test carried out on non-nutrient blood agar prepared from sheep erythrocytes sensitized with equi factor of *Rhodococcus equi* for the detection of antibodies to phospholipase D (PLD) of *A. haemolyticum*. When testing 433 sera from 404 patients with signs of acute tonsillitis, these authors found antibodies to PLD in 28 patients (6.9%). Among 116 sera from individuals without signs of pharyngitis, antibodies to PLD were detected in only one case (0.9%).

Using a similar assay, Skalka et al. (1998) investigated sera of humans with spontaneous *A. haemolyticum* infections and mice experimentally infected with this organism and found that the titers of neutralizing antibodies to the homologous PLD were always higher than those to the heterologous PLD produced by *Corynebacterium pseudotuberculosis*.

Using SDS-PAGE and Western blot analyses, specific antibodies to *A. haemolyticum* could be

demonstrated in sera from patients with acute infections or from convalescents (Nyman et al., 1997). These antibodies reacted primarily with four cell wall-associated proteins with estimated molecular weights of 80, 60, 50, and 30 kDa, respectively.

Epidemiology

In contrast to essentially all other members of the family Actinomycetaceae, *Arcanobacterium* species may cause inflammatory diseases that are not exclusively endogenous in origin but may well be transmitted from animal to animal, from animals to humans, or even between humans. This is especially true for *A. pyogenes*, which is able to induce mastitis in cows and may, therefore, appear in the milk. In cows with undiagnosed mastitis, the organism may then easily be transmitted to other animals or humans (Mazura, 1989).

Bovine mastitis occurs throughout the year, but infections due to *A. pyogenes* were encountered most often in late autumn, winter and spring (Jones and Ward, 1989; Waage et al., 1999). At parturition, the causative agents of mastitis such as *Escherichia coli*, *A. pyogenes*, streptococci and staphylococci were isolated in about equal frequencies, but in the late lactation period *E. coli* predominated (Jones and Ward, 1989). Mastitis in cattle has often been associated with insufficient milking hygiene or drug instillations into the teats, but *A. pyogenes*, in contrast to certain other mastitis agents, may also cause epizootic outbreaks of "summer mastitis" in heifers and even in young calves that are too young for breeding (Lean et al., 1987). In these latter cases, a large number of flies, intersucking of calves, or preceding viral disease was assumed to influence the outbreak. Furthermore, various forms of teat lesions were found to increase the risk of mastitis due to *A. pyogenes* and other organisms (Mulei, 1999).

Arcanobacterium pyogenes also is a typical and common agent of peritonitis and pleuritis in swine and of pneumonia in calves (Glage, 1903; Roberts, 1968; Reddy et al., 1982; Seno and Azuma, 1983; Vogel et al., 2001). Reliable epizootic conclusions cannot be drawn on the basis of occasional reports on *A. pyogenes* infections of other body sites or other domestic or feral animals.

The same is true for human infections due to this organism or *A. haemolyticum* and for infections caused by the other *Arcanobacterium* species. Nevertheless, Kotrajaras and Tagami (1987), when investigating the role of *A. pyogenes* in the etiology of endemic leg ulcers in Thailand, found that skin injuries followed by *A. pyogenes* infection were important for the development of this

human disease. In addition, Oriental-eye flies were assumed to carry the pathogen to the traumatized skin. As far as human bacterial pharyngitis is concerned, Linder (1997) reported that 0.5–2.5% of this infection was due to *A. haemolyticum*. In a more detailed study of a pediatric and adolescent population, Mackenzie et al. (1995) found that the incidence of infection caused by this organism was highest in the 15–18 year-old age group (2.5%). No single isolate of *A. haemolyticum* was cultured from healthy control persons (2241 healthy students). Comparable results were obtained in a study on army conscripts (Carlson et al., 1995b), with an overall incidence of 1.4% in individuals with sore throat, while 23% of this study group yielded growth of β -hemolytic streptococci.

Pathogenicity

ANIMAL INFECTIONS *Arcanobacterium pyogenes* is primarily an animal pathogen. The pyogenic pathological conditions caused by this organism in domestic animals most typically include mastitis in cows, often associated with *Peptoniphilus* (*Peptostreptococcus indolicus*), and peritonitis and pleuritis in swine (Glage, 1903; Roberts, 1968; Reddy et al., 1982; Seno and Azuma, 1983). *Arcanobacterium pyogenes* was also found to be etiologically involved in pneumonia in calves (Vogel et al., 2001), in hematogenous osteomyelitis in cattle (Firth et al., 1987), in purulent osteomyelitis in fattening pigs (Burgi et al., 2001), in a pyothorax in a one-month-old female kitten (Gulbahar and Gurtuk, 2002), in chronic otitis externa in a cat and urinary tract infection in a dog (Billington et al., 2002a), in hypertrophic osteopathy in a dog, in the retention of fetal membranes in ewes (Tzora et al., 2002), in facial and mandibular abscesses in blue duiker, often associated with *Fusobacterium necrophorum* (Roeder et al., 1989), in intracranial abscesses in white-tailed deer (Baumann et al., 2001) and a steer (Strain et al., 1987), and in lymphadenitis in camels (Moustafa, 1994). The development of renal medullary amyloidosis in Dorcas gazelles also appeared to be related to chronic or recurring *A. pyogenes* infections (Rideout et al., 1989).

Experimental mastitis induced by intramammary challenge with *A. pyogenes* was found to be more severe in dry than in lactating glands and was very difficult to eliminate in the dry period even by antibiotic treatment, whereas lactating glands recovered more easily either spontaneously or after administration of antibiotics. Combined infections of *A. pyogenes* with *Peptoniphilus indolicus* took an especially severe clinical course and showed a higher frequency of systemic involvement (Hillerton and Bramley, 1989).

Arcanobacterium haemolyticum has been known as an occasional cause of infections in farm animals (Collins and Cummins, 1986). Recently, the organism was identified as one of the pathogens responsible for mandibular and maxillary abscesses in pet rabbits (Tyrrell et al., 2002).

Of the remaining *Arcanobacterium* species, *A. bernardiae* has as yet only been isolated from human sources. *Arcanobacterium phocae* has been recovered in mixed culture from various tissues and fluids of common seals (*Phoca vitulina*) and gray seals (*Halichoerus grypus*), but its pathological significance remains unclear. *Arcanobacterium pluranimalium* has been isolated from the spleen of a dead harbor porpoise and a lung abscess of a dead fallow deer (Lawson et al., 2001a), and *A. hippocoleae* has been, cultured from a female Arab horse with vaginal discharge (Hoyle et al., 2002b).

HUMAN INFECTIONS Human infections due to *A. pyogenes* usually present as acute pharyngitis, urethritis or as cutaneous or subcutaneous suppurative processes (Barksdale et al., 1957; Collins and Jones, 1982a; Reddy et al., 1982; Gahrn-Hansen and Frederiksen, 1992), but bacteremia has also been reported (Barnham, 1988). Additional human *A. pyogenes* infections include septic arthritis in a diabetic farmer (Lynch et al., 1998) and endemic leg ulcers in Thailand (Kotrajara and Tagami, 1987).

The clinical symptoms of *A. haemolyticum* infections are similar, this organism being predominantly isolated from pharyngeal infections, skin lesions and septicemia (Collins and Cummins, 1986; Dethy et al., 1986; Moreno-Montesinos et al., 1989; Carlson et al., 1994e; Gaston and Zurowski, 1996; White and Foshee, 2000; Jurankova et al., 2001) with and without metastatic abscess formation (Dieleman et al., 1989). Primary deep-seated abscesses (Barnham and Bradwell, 1992), cellulitis including a fulminant tubo-ovarian soft tissue infection (in coculture with fusobacteria; Batisse-Milton et al., 1995) and an orbital cellulitis (Ford et al., 1995), surgical wound infections, an infected foot wound, and endocarditis due to this organism have also been reported (Ritter et al., 1993; Esteban et al., 1994; Alos et al., 1995; Skov et al., 1998; Dobinsky et al., 1999).

Arcanobacterium bernardiae has been isolated from various clinical sources including blood, abscesses, and eye infections (Funke et al., 1995b). More recently, urinary tract infections and septic arthritis due to this organism were also described (Adderson et al., 1998; Lepargneur et al., 1998). The remaining *Arcanobacterium* species appear to occur only in animals.

TREATMENT OF *ARCANOBACTERIUM* INFECTIONS AND ANTIMICROBIAL SUSCEPTIBILITY Studies on the antibiotic susceptibility of *A. pyogenes* were mainly performed on strains of animal origin. Yoshimura et al. (2000), investigating the resistance patterns of 49 bovine and porcine isolates from Japan, reported that all of the isolates were highly susceptible to benzyl penicillin and ampicillin and also to other penicillins and cepheems. In contrast, varying numbers of strains were resistant to dihydrostreptomycin, gentamicin and oxytetracycline. Resistance to dihydrostreptomycin appeared to be more pronounced among porcine (85.7%) than among bovine (52.4%) isolates; resistance to gentamicin occurred in only 7.1% of the bovine strains; oxytetracycline resistance was also more frequently encountered among porcine (85.7%) than among bovine (57.1%) isolates.

All bovine isolates were susceptible to erythromycin and lincomycin, but two porcine strains were resistant to both antibiotics. Chloramphenicol as well as florfenicol and thiamphenicol were all active against most of the animal *A. pyogenes* isolates. In analogy to other Actinomycetaceae, the fluoroquinolones enrofloxacin and ofloxacin were not as active against this organism as penicillins and macrolides were.

In a study on the resistance of *A. pyogenes* isolates from the United States to macrolides, lincosamides and tetracyclines, Trinh et al. (2002), using a broth microdilution test, found that 25% were resistant to the former two groups and 41.7% to the latter class of antibiotics. Tetracycline resistance could be related to the presence of a gene which was highly similar at the DNA level (92% identity) to the *tet(W)* gene from the rumen bacterium *Butyrivibrio fibrisolvens* encoding a ribosomal protection tetracycline resistance protein (Billington et al., 2002b).

Arcanobacterium haemolyticum was reported to be resistant to oxytetracycline but susceptible to trimethoprim-sulfamethoxazole and amikacin (Schofield and Schaal, 1981; Collins and Cummins, 1986). Susceptibility to β -lactam compounds was reported by Carlson et al. (1994c) and also by Arikan et al. (1997) from Turkey, together with susceptibility to vancomycin, erythromycin, azithromycin, clindamycin, doxycycline and ciprofloxacin. However, according to these authors *A. haemolyticum* was resistant to trimethoprim-sulfamethoxazole.

The antibiotic susceptibility pattern of *A. bernardiae* as reported in the original description of seven strains of this species (Funke et al., 1995b) was as follows: All strains were susceptible to clindamycin, erythromycin, penicillin G, rifampin, tetracycline and vancomycin. Most of the strains were susceptible to gentamicin but resistant to ciprofloxacin.

Detailed studies on the antibiotic susceptibility of the remaining *Arcanobacterium* species have not been reported.

VIRULENCE FACTORS OF *ARCANOBACTERIUM* SPECIES *Arcanobacterium pyogenes* has been shown to produce soluble toxic and hemolytic activities which can be neutralized by antitoxin and which are fatal to mice and rabbits after intravenous injection (Lovell, 1944; Reddy et al., 1982). This hemolytic exotoxin, called "pyolysin" (PLO), belongs to the thiol-activated, cholesterol-binding pore-forming family of toxins (Billington et al., 2001) and has a molecular mass of 56 kDa (Ikegami et al., 2000). Inactivation of the *plo* gene results in a significant reduction in virulence of *A. pyogenes* (Jost et al., 1999). Furthermore, a recombinant PLO-based subunit vaccine protected mice from experimental *A. pyogenes* infection. Analysis of the functional domains of this toxin revealed that the N-terminal region of PLO was important for the hemolytic activity (Imaizumi et al., 2001).

Additional virulence factors of *A. pyogenes* are two different neuraminidases that obviously play a role in adhesion of this organism to host epithelial cells (Jost et al., 2001; Jost et al., 2002), as do neuraminidases of other bacterial pathogens. Acyl-neuraminate pyruvate lyase is also produced (Müller, 1973). In cattle with necrotizing bronchopneumonia, *A. pyogenes* induces the expression of nitric oxide synthase (iNOS) (Fligger et al., 1999), the expressing cells being largely restricted to the cellular zone surrounding necrotic areas. The ability of *A. pyogenes* to bind to human α_2 -macroglobulin and haptoglobin may further contribute to its pathogenicity (Lämmler et al., 1985).

Arcanobacterium haemolyticum produces a phospholipase D (PLD) as one of its soluble toxins (Cuevas and Songer, 1993). This toxin is a protein of approximately 31.5 kDa with a pI of about 9.4 and is related to, but not identical with, the phospholipases D of *Corynebacterium pseudotuberculosis* and *C. ulcerans*. Sequence comparison of PLD coding regions revealed 65% DNA-DNA similarity of the *pld* genes of these three species. Comparison of the amino acid sequences of *C. pseudotuberculosis* bv. *equi*, *C. pseudotuberculosis* bv. *ovis*, *C. ulcerans* and *A. haemolyticum* PLDs showed that these four enzymes share 64–97% similarity (McNamara et al., 1995).

Like *A. pyogenes*, *A. haemolyticum* produces neuraminidase and acylneuraminate pyruvate lyase (Müller, 1973), and both species also possess DNase activity, which may contribute to their pathogenicity as well. In addition, the findings of Osterlund (1995) suggest that *A.*

haemolyticum may be able to invade host cells and to survive intracellularly.

Virulence factors of the other *Arcanobacterium* species have not been studied.

Genetics

Electroporation was used to transform *A. pyogenes* (Jost et al., 1997). The transformants were able to express resistance to chloramphenicol, erythromycin, kanamycin and streptomycin encoded by the introduced plasmid DNA.

The Genus *Varibaculum*

The genus *Varibaculum* with the single species *Varibaculum cambriense* was proposed by Hall et al. (2003e) for anaerobic, catalase-negative, Gram-positive diphtheroidal bacteria isolated from human sources on the basis of phenotypic and molecular methods. For the sake of grammatical correctness, the species had to be renamed *Varibaculum cambriense* (see Phylogeny).

Phylogeny and Taxonomy

16S rRNA gene sequence analysis of five strains of *V. cambriense* revealed that the almost complete sequences of these strains were nearly identical (99.1–100% sequence similarity). The phylogenetic placement confirmed their association with members of the family Actinomycetaceae, supporting phenotypic, in particular morphological, resemblance. The new genus contributes further to the phylogenetic diversity of the family (Hall et al., 2003e), as *Varibaculum* forms a relatively long and distinct line of descent, about equidistantly related to *Actinomyces neuii* and *Mobiluncus* species (Hoyles et al., 2003).

MORPHOLOGICAL CHARACTERISTICS Cells of *Varibaculum cambriense* are short, straight or curved, diphtheroid rods which stain Gram-positive and are non-acid-fast and nonmotile (Fig. 32). Colonies after 48 h of anaerobic incubation on horse blood-containing complex media are pinpoint, convex, glistening, translucent white or gray with entire edges (Fig. 33). No hemolysis is observed.

CHEMOTAXONOMIC PROPERTIES Whole-cell protein profiling using PAGE demonstrated a considerable phenotypic coherence of members of the species *V. cambriense* and their clear distinctness from *Mobiluncus* species (Hall et al., 2003e). The G+C content of the DNA is 51.7 mol%.

Fig. 32. *Varibaculum cambriense*; Gram-stained smear from a mature colony (brain heart infusion agar, 14 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

Fig. 33. *Varibaculum cambriense*; mature, slightly raised, translucent colony without internal structures; micrograph in transmitted light (brain heart infusion agar, 14 days at $36 \pm 1^\circ\text{C}$, and Fortner's method).

PHYSIOLOGICAL PROPERTIES *Varibaculum cambriense* is anaerobic and catalase-negative. Major end products of its fermentative glucose metabolism are lactic and succinic acids.

Other physiological properties are summarized in Table 14. Markers characteristic of the species are acid production from glucose and only a few additional carbohydrates, hydrolysis of hippurate (but not of esculin, gelatin and starch), and α -glucosidase (but no urease) activity. Nitrate is reduced by the majority of strains (Table 14).

Isolation and Cultivation

Varibaculum cambriense appears to grow well on Columbia agar supplemented with 5% horse serum at $36 \pm 1^\circ\text{C}$ under anaerobic conditions. Alternatively, Fastidious Anaerobe Agar (LabM, Bury, UK) may be used. Anaerobic incubation requires 48–72 h until colonies are easily visible. Strains may grow well or poorly in air plus 5%

CO₂, but they grow poorly or not at all in air, thus behaving like typical members of the Actinomycetaceae.

Identification

Apart from 16S rRNA gene sequencing, identification of *V. cambriense* may be achieved by a set of morphological and physiological characters. Cellular and colonial morphology, growth conditions together with lack of catalase production, positive nitrate reduction, and lactic and succinic acids as major end products of glucose fermentation may form the basis of recognizing *V. cambriense*. Additional differential characters may be selected from Table 14.

Pathogenicity

Given the fact that only 15 strains of *V. cambriense* have been encountered so far, it is not surprising that essentially nothing is known about the habitat, ecology and epidemiology of these organisms.

The strains were isolated from human abscesses (1 brain abscess following ear and mastoid problems together with a complex anaerobic flora; 1 postauricular abscess; 1 large ischiorectal abscess; 1 submandibular abscess; 3 breast abscesses; 1 cheek abscess; and 2 from a non-characterized abscess), intrauterine contraceptive devices or vaginal swabs (3 strains), and hidradenitis and a fistula (1 strain each). Several isolates were cultured together with other potentially pathogenic bacteria, and others were obtained without clear indications of an inflammatory process. Therefore, the pathogenicity of *V. cambriense* to humans remains to be elucidated.

The Genus *Mobiluncus*

Unlike any other member of the family Actinomycetaceae, *Mobiluncus* species are curved, non-branching, motile, anaerobic bacteria that stain Gram-variable or Gram-negative. Such *Vibrio*-like organisms were already seen in vaginal secretions by Krönig as early as 1895 and were first isolated in pure culture from vaginal and uterine specimens of a woman suffering from postpartum endometritis by Curtis in 1913. Prévot (1940), in his manual on classification and identification of anaerobic bacteria, used the designation "*Vibrio mulieris*" for these bacteria of Curtis. However, no further description of curved rod-shaped bacteria from the female genital tract was published until Moore's characterization of "anaerobic vaginal vibrios" (Moore, 1954). Similar or identical "vibrions succinoproducers" were separated into two groups by

Durieux and Dublanchet (1980) on the basis of cellular morphology, fermentation of glucose, and reduction of nitrate.

In 1984, Spiegel and Roberts as well as Hammann et al., referring to "*Vibrio mulieris*" of Prévot (1940), proposed the genus designations "*Falcivibrio*" and "*Mobiluncus*," respectively, for two different species of anaerobic curved rods from the human vagina. Although the genus designation *Falcivibrio* appeared first in the literature, it was not validated first, so that *Mobiluncus* has priority. Recently, Hoyles et al. (2003), in a polyphasic taxonomic study, formally proposed to transfer the members of the genus *Falcivibrio* to the genus *Mobiluncus*. These organisms are etiologically involved in a syndrome called "bacterial vaginosis," "nonspecific vaginitis," "*Haemophilus vaginalis* vaginitis" (Gardner and Dukes, 1955), anaerobic vaginosis (Blackwell et al., 1983), or "amine colpitis."

Taxonomy

Although members of the genus *Mobiluncus* appeared to be clearly distinct from the Actinomycetaceae, the Bacteroidaceae, and the Propionibacteriaceae phenotypically, Spiegel and Roberts (1984a) tentatively placed them in the family Bacteroidaceae. They noted, however, that *Mobiluncus* bacteria, despite the variable to negative reaction in the Gram stain, revealed a multilayered Gram-positive cell wall under the electron microscope and did not possess an outer membrane characteristic of Gram-negative bacteria. A more detailed chemical analysis of *Mobiluncus* cell walls (Carlone et al., 1986) confirmed that their composition was not Gram-negative. However, in view of the morphological characteristics, it was still surprising that the results of partial reverse transcriptase sequencing of 16S rRNA suggested that the genus *Mobiluncus* was not a member of the family Bacteroidaceae, but apparently belonged to the order Actinomycetales (Lassnig et al., 1989). As outlined in the Phylogeny section, this affiliation has definitely been confirmed since then.

Thus far, the genus *Mobiluncus* only comprises the two species described by Spiegel and Roberts (1984a) under the designations *Mobiluncus curtisii* and *M. mulieris*. These correspond to the organisms described by Hammann et al. (1984) as "*Falcivibrio vaginalis*" (*M. curtisii*.) and "*Falcivibrio grandis*" (*M. mulieris*; Hoyles et al., 2003).

The separation of two subspecies (*M. curtisii* subsp. *curtisii* and *M. curtisii* subsp. *holmesii*) within *M. curtisii* was chiefly based upon a few phenotypic differences but was not supported by DNA-DNA similarity studies (Spiegel, 1992) or comparative partial 16S rRNA gene analysis

(Tiveljung et al., 1996). However, the analysis of surface antigens of *Mobiluncus* using monoclonal antibodies in an enzyme-linked immunosorbent assay and indirect immunofluorescence revealed four monoclonal antibodies (MAbs), and thus surface components, that appeared to be subspecies-specific for *M. curtisii* subsp. *curtisii* (Fohn et al., 1988). One MAb reacted with an epitope present on *M. curtisii* subsp. *holmesii* and *M. mulieris* but not on *M. curtisii* subsp. *curtisii*. A more detailed analysis of the 16S rRNA genes of *Mobiluncus* species showed that so-called “atypical *Mobiluncus* strains” could be separated from both *M. curtisii* and *M. mulieris* (Tiveljung et al., 1995), and Hoyles et al. (2003) stated that *M. curtisii* should be considered a single but complex species which cannot be differentiated into distinct subspecies on the basis of physiological markers alone.

MORPHOLOGICAL CHARACTERISTICS *Mobiluncus* cells are Gram-variable to Gram-negative, curved rods with tapered ends, do not form endospores, and occur singly or in pairs producing a gull wing appearance. They are motile by means of multiple, either subpolar or more centrally located, flagella (Spiegel and Roberts, 1984a; Spiegel, 1992). *Mobiluncus curtisii* has one to six flagella per cell with a common origin, while *M. mulieris* possesses one to eight flagella with multiple origins (Hammann et al., 1984; Spiegel, 1992). *Mobiluncus curtisii* subsp. *curtisii* was reported to migrate through soft (0.25%) agar, whereas *M. curtisii* subsp. *holmesii* was not; however, migration through soft agar is also variable in *M. mulieris* (Spiegel and Roberts, 1984a), while this feature was recently shown not to exactly correspond to *M. curtisii* subsp. *curtisii* (Hoyles et al., 2003).

Electron micrographs revealed that *Mobiluncus* species possess a multilayered Gram-positive cell wall lacking an outer membrane. The thinness of these walls was considered to be the reason for the tendency of mobiluncii to stain Gram-negative (Spiegel and Roberts, 1984a). Pili (fimbriae) were not observed (Hammann et al., 1984).

Cells of the two *Mobiluncus* species differ considerably in size: While *M. curtisii* cells are $<0.5\ \mu\text{m}$ wide and on average $1.7\ \mu\text{m}$ long rods (Fig. 34), *M. mulieris* cells are significantly longer, measuring $<0.5\ \mu\text{m}$ in width but $2.9\ \mu\text{m}$ in mean length (Fig. 35).

Colonies of both species are white to gray or slightly yellowish, translucent, smooth, convex, and entire, and reach a maximum diameter of 1–4 mm after 5 days of incubation (Fig. 36).

CHEMOTAXONOMIC PROPERTIES The G+C content of the DNA of the *Mobiluncus* type strains is 49–

Fig. 34. *Mobiluncus curtisii* subsp. *holmesii*; Gram-stained smear from a mature colony (Columbia sheep blood agar, 14 days at $36 \pm 1^\circ\text{C}$, and GasPak jar).

Fig. 35. *Mobiluncus mulieris*; Gram-stained smear from a mature colony (Columbia sheep blood agar, 14 days at $36 \pm 1^\circ\text{C}$, and GasPak jar).

Fig. 36. *Mobiluncus mulieris*; mature, slightly raised, translucent colony with finely granular internal structures; micrograph in transmitted light (Columbia sheep blood agar, 14 days $36 \pm 1^\circ\text{C}$, and GasPak jar).

52 mol% (Spiegel and Roberts, 1984a), although values as high as 53.5 ± 0.6 for *M. mulieris* and 55.2 ± 0.6 for *M. curtisii* have been reported (Hammann et al., 1984).

Lipopolysaccharide (LPS) could not be demonstrated, although four *Mobiluncus* strains were observed in the *Limulus* amoebocyte lysate (LAL) test to have activities intermediate between those of "*Corynebacterium genitalium*" (no detectable LAL reactivity) and those of *Pseudomonas aeruginosa* (Carlone et al., 1986).

Detailed analysis of the carbohydrate content of hydrolyzed whole cells of *Mobiluncus* strains revealed the absence of 2-keto-3-deoxyoctonate (KDO) and heptose but the presence of rhamnose, galactose, glucosamine, and muramic acid in comparable amounts.

Mobiluncus mulieris extracts contained approximately three times as much ribose as the *M. curtisii* strains, while the latter had two times as much glucose as the *M. mulieris* isolates. Mannosamine was detected in both *M. curtisii* subsp. *curtisii* and *M. curtisii* subsp. *holmesii* but was not found in the *M. mulieris* strains. Galactosamine was present in both species, but in the *M. mulieris* strains, only in amounts of less than 0.5%.

The fatty acid profile of *Mobiluncus* strains consisted of tetradecanoic (14:0), hexadecenoic (16:1), hexadecanoic (16:0), heptadecanoic (17:0), octadecadienoic (18:2), octadecenoic (18:1), and octadecanoic (18:0) acids (16:0, 18:2, and 18:1 being the major components in all strains tested). Fatty acid aldehydes were not detected by Carlone et al. (1986) but were reported by Skarin et al. (1982b); hydroxylated fatty acids were also not found.

Electrophoretic patterns of bacterial cellular proteins were often found to possess differential power when traditional phenotypic markers did not provide clear-cut species-specific profiles. However, determination of PAGE protein patterns requires highly standardized conditions to provide reproducible results. Thus, several authors obtained conflicting results (Vetere et al., 1987; Spiegel, 1992) concerning number and specificity of protein bands in *Mobiluncus* species. More recently, however, Drouet et al. (1991), studying 35 *Mobiluncus* strains (including three reference strains), reported "species-related" protein patterns as well as intraspecies variation possibly useful for epidemiological purposes. Combination of SDS-PAGE and immunoblotting (Schwebke et al., 1990) demonstrated a strikingly high degree of protein heterogeneity within the genus *Mobiluncus*, suggesting that further taxonomic divisions might be appropriate. Similar conclusions were drawn from the results of a combined morphological, biochemical and serological study performed by Garlind et al. (1989).

PHYSIOLOGICAL PROPERTIES At least for primary isolation, mobilunci require anaerobic growth conditions (Spiegel, 1992). However, after mul-

tipile transfers, growth has also been reported in 10% CO₂ or 5% oxygen (Hammann et al., 1984). The optimum temperature for multiplication is 35–37°C (Holst et al., 1982; Hammann et al., 1984; Spiegel and Roberts, 1984a), and there is poor or no growth at 20, 43, or 45°C (Durieux and Dublanchet, 1980; Peloux and Thomas, 1981; Holst et al., 1982). Heating at 55°C for 15 min kills *Mobiluncus* cells (Curtis, 1913). Reports on growth at 22, 27, 30, or 42°C are contradictory (Spiegel, 1992).

When growing in peptone yeast extract glucose medium (PYG), succinic, acetic, and lactic acids are the major fermentation end products (Holst et al., 1982; Hammann et al., 1984; Spiegel and Roberts, 1984a; Vetere et al., 1987). Addition of rabbit serum and glycogen to peptone yeast extract broth (PY) enhances the production of acetic and succinic acids as compared to the same medium supplemented with rabbit serum and glucose or rabbit serum alone (Spiegel and Roberts, 1984a). When fumarate is added to the medium, malic acid is produced (Hammann et al., 1984; Spiegel and Roberts, 1984a).

Most of the metabolic activities of *Mobiluncus* species have been included in Table 14. Note, however, that the determination of such "biochemical" characters is highly method-dependent, so that there is still some controversy about some of the physiological properties (Spiegel, 1992; Hoyles et al., 2003). This may be especially true for the detection of weak or very weak acid production from carbohydrates, which may be influenced by size and viability of the inoculum, methods used for the fermentation tests, or techniques used for obtaining anaerobic growth conditions.

Physiological properties that are characteristic of the genus *Mobiluncus* and that may aid in the differentiation of the species of this genus are summarized in Table 16.

Habitat and Ecology

Numerous studies using a variety of methods such as microscopy of wet mounts or immunofluorescence-labeled smears, culture, or DNA probes were performed to assess the occurrence of *Mobiluncus* species or simply motile, curved rods in human vaginal secretions. Such curved rods were detected in up to 7.2% of unselected women undergoing gynecological examinations (Popp, 1977; Dropsy, 1978). However, these organisms were mainly present in women complaining of foul-smelling discharge who also had increased numbers of epithelial cells in their vaginal fluids without an elevated level of leukocytes. These are key symptoms of a condition called "bacterial vaginosis" (Gardner and Dukes, 1955; Amsel

Table 16. Characteristics useful for identifying and differentiating *Mobiluncus* species.

Characteristic	<i>Mobiluncus curtisii</i> subsp.		<i>Mobiluncus mulieris</i>
	<i>curtisii</i>	<i>holmesii</i>

Symbols and abbreviations: +, positive/present; –, negative/absent; d, positive or negative; +/-, usually positive; -/+, usually negative; Su, succinic acid; Ac, acetic acid; and La, lactic acid.

From Spiegel and Roberts (1984).

et al., 1983; see the Pathogenicity section in this Chapter), in which detection rates of mobilunc between 10.9% and 77% were reported (Durieux and Dublanchet, 1980; Durieux and Dublanchet, 1981; Spiegel et al., 1983b; Holst et al., 1984a; Holst et al., 1984b; Holst et al., 1984c; Roberts et al., 1984; Sprott et al., 1984; Thomason et al., 1984; Hallén et al., 1987; Hallén et al., 1988; Teo et al., 1987; Schnadig et al., 1989; Hillier et al., 1991; Kaneko et al., 1992). Using PCR, the percentage of women with bacterial vaginosis even reached 84.5% (Schwebke and Lawing, 2001). In contrast, very little is known about the occurrence of mobilunci in healthy women and possible other natural reservoirs.

With no signs of bacterial vaginosis, *Mobiluncus* species were detected in human vaginal secretions either not at all or only in low numbers (and in a small proportion, i.e., 6%; Skarin and Mårdh, 1982; Spiegel et al., 1983b; Sprott et al., 1983; Hallén et al., 1987). These findings were confirmed, to some extent, in recent studies (Hillier et al., 1991; Kaneko et al., 1992; Schwebke and Lawing, 2001). However, while Hillier et al. (1991) and Kaneko et al. (1992), using conventional bacteriological techniques, found the prevalence of *Mobiluncus* species in healthy women was 0.7–4.0%, Schwebke and Lawing (2001), using a PCR-based methodology, found that 38% of women without infection harbored these organisms. *Mobiluncus curtisii* was rarely detected in this latter group. Notably, in the study of Schwebke and Lawing (2001), sen-

sitivity and specificity of Gram stain compared with PCR were 46.9% and 100%, respectively. Thus, *Mobiluncus* species appear to be more common in the vagina of healthy women than assumed before, with *M. mulieris* predominating.

Hallén et al. (1988) first studied simultaneous colonization of vagina and rectum in women attending a sexually transmitted diseases department. Of 43 women showing symptoms of bacterial vaginosis (BV), 32 had *Mobiluncus* species in the vaginas and 23 in the rectum. In 20 individuals, the same *Mobiluncus* species was found in both sites, and two only showed rectal colonization. In a comparative study of the occurrence of the four organisms associated with BV (namely, *Mobiluncus mulieris*, *M. curtisii*, *Mycoplasma hominis* and *Gardnerella vaginalis*) in 374 persons (women with and without BV, their male sexual partners, four homosexual men, and children), Holst (1990) reported that all four species were isolated from the recta of 45–62% of women with BV and of 10–14% of women without BV. These organisms also occurred in the recta of males and children. Vaginal occurrence, in this study, was restricted to women with BV (97%).

The prevalence of *Mobiluncus* species in males has been investigated by Hillier et al. (1990), Holst (1990), and Vetere et al. (1987). Hillier et al. (1990) found that semen samples from 37 men attending a special infertility clinic contained nearly always aerobic or anaerobic bacteria or both with a mean isolation rate of 5.2 strains

per seminal specimen. Predominant organisms were coagulase-negative staphylococci (89%), α -hemolytic streptococci (65%), coryneforms (86%), anaerobic streptococci (62%), Bacteroidaceae (27%) and *Gardnerella vaginalis* (19%). *Mobiluncus* species were recovered from fewer than 10% of the samples. Already in 1987, Vetere et al. had also reported one *Mobiluncus* isolate from seminal fluid from an infertile man. In the study of Holst (1990), mobiluncii were infrequently isolated from genital samples of 135 males. However, these organisms were cultured from the urethrae and coronal sulci of 10 out of 44 male consorts of women showing symptoms of BV. After two weeks of condom use during sexual intercourse, only *Mycoplasma hominis* remained in the urethra of one man, but the *Mobiluncus* species had completely disappeared.

Other extragenital occurrence of *Mobiluncus* species in men has always been related to disease and will therefore be discussed in the Pathogenicity section. Environmental sources of the organisms have not been reported; however, Doyle et al. (1991) stated that *Mobiluncus curtisii* subsp. *curtisii* belonged to the most common bacterial isolates from the vaginas of 37 healthy rhesus macaques (*Macaca mulatta*).

Isolation, Cultivation and Detection

As in many other members of the family Actinomycetaceae, *Mobiluncus* species require organically complex media and a suitable gaseous environment for good growth. As they grow slowly, they are easily overgrown by more rapidly multiplying organisms simultaneously present. Selective media or principles therefore facilitate the isolation and recognition of mobiluncii.

NONSELECTIVE SOLID AND LIQUID CULTURE MEDIA Agar media usually yield better growth of *Mobiluncus* species than do liquid culture media. Several general purpose solid media were reported to support growth of mobiluncii including Columbia agar, brain heart infusion agar, DST agar (Oxoid), peptone yeast extract glucose agar, and Schaedler agar (Spiegel, 1992). Growth on these media is stimulated by the addition of 4–15% horse (Moore, 1954; Sprott et al., 1982), human (Curtis, 1913; Moore, 1954; Sprott et al., 1983; Hammann et al., 1984), sheep (Curtis, 1913; Moore, 1954; Hammann et al., 1984; Smith and Moore, 1988), guinea pig (Moore, 1954), goat (Curtis, 1913), or rabbit blood (Smith and Moore, 1988). Addition of serum is also stimulatory (Spiegel, 1992). Supplementation with vitamin K and hemin is not necessary (Sprott et al., 1983).

Growth of *Mobiluncus* species in liquid media is usually poor or at least poorer than on solid

media (Vetere et al., 1987; Taylor-Robinson and Taylor-Robinson, 2002). Addition of several putative growth factors does not necessarily improve multiplication of the organisms (Taylor-Robinson and Taylor-Robinson, 2002), although supplementation with serum from horse (Moore, 1954; Durieux and Dublanchet, 1980; Durieux and Dublanchet, 1981; Taylor-Robinson and Taylor-Robinson, 2002), rabbit (Spiegel et al., 1983b; Spiegel and Roberts, 1984a), or cattle (Taylor-Robinson and Taylor-Robinson, 2002) was found to be beneficial.

More important for acceptable growth yields in liquid culture is, however, the selection of an appropriate commercial basal medium. From nine media evaluated by Taylor-Robinson and Taylor-Robinson (2002), only two appeared to be satisfactory. These were Columbia blood broth (Oxoid) and peptone starch dextrose broth (Oxoid) supplemented with 10% horse serum. Provided that a strain is chosen that multiplies easily, these media allow the generation of sufficient amounts of cell mass for, e.g., antigen production or the analysis of virulence factors.

PRETREATMENT PROCEDURES In view of the fastidiousness and the slow growth of *Mobiluncus* species, isolation of the organisms from their natural habitats is hampered by their occurrence with a variety of other, often rapidly multiplying microbes that tend to overgrow them. Thus, pretreatment techniques and selective media are required to obtain optimum detection rates.

Pretreatment measures have been used in conjunction with selective and nonselective culture media. Alkaline pretreatment (Påhlson and Forsum, 1985; Påhlson et al., 1986b) was found to allow survival of more than 90% of *Mobiluncus* cells exposed to pH 12 buffer for 30 and 5 min, respectively. In contrast, less than 80% of other vaginosis-associated organisms survived when clinical specimens were treated in the same way. After exposure to alkaline conditions, the samples were inoculated onto a nonselective medium consisting of brain heart infusion agar supplemented with vitamin K, hemin, and 5% sheep blood. This procedure led to a *Mobiluncus* recovery rate of 58% as compared with 17% without alkaline pretreatment (Påhlson et al., 1986b).

An alternative pretreatment method is the cold-enrichment technique introduced by Smith and Moore (1988) in combination with the application of selective culture media. When specimens are stored at 4–5°C for 1–21 h prior to cultivation immediately after they had been obtained, the recovery rate of mobiluncii increased from 18% to 77% compared with samples primarily held at room temperature. These findings were confirmed by Menolascina et al. (1999).

SELECTIVE CULTURE MEDIA A variety of antibiotic or other inhibitory additives has been tried to make agar media selective for *Mobiluncus* species. These include colistin plus nalidixic acid (Durieux and Dublanchet, 1980; Durieux and Dublanchet, 1981), trimethoprim-sulfamethoxazole plus polymyxin B, tinidazole plus colistin or nalidixic acid (Holst et al. [1984a], cited by Spiegel [1992]), and colistin, nalidixic acid, tinidazole, and Nile blue A (Spiegel, 1992). When using tinidazole it has to be noted that concentrations >4 mg/liter of this drug may be inhibitory to some strains of *M. mulieris* (Spiegel, 1987).

Details on the composition and preparation of the selective media used in conjunction with the cold-enrichment technique (Smith and Moore, 1988) are given below.

Rlk Medium (Smith and Moore, 1988)

Columbia CNA agar (BD)	42.5 g
Yeast extract	6.0 g
Peptone	20.0 g

Dissolve in and dilute up to 1 liter with distilled water and autoclave. After cooling, add laked rabbit or sheep blood (50.0 ml), tinidazole (48.0 mg), and nalidixic acid (20.0 mg).

Air-dry 1–2 days and incubate under reducing conditions 1–7 days before inoculation.

SA Medium (Smith and Moore, 1988)

Columbia CNA agar (BD)	42.5 g
Laked rabbit or sheep blood	16.0 ml
Rabbit serum	20.0 ml

Dissolve in and dilute up to 1 liter with distilled water and autoclave. After cooling, add tinidazole (48.0 mg) and nalidixic acid (20.0 mg). Air-dry 1–2 days and incubate under reducing conditions 1–7 days before inoculation.

Further selective media were reported by Spiegel and Krueger (1986) and Holst et al. (1984a).

Mobi Agar (Spiegel and Krueger [1986], cited by Spiegel [1992])

Columbia broth (Difco/BD)	35.0 g
Bacto agar (Difco/BD)	15.0 g
Cysteine · HCl	0.4 g
Soluble starch (Difco/BD)	10.0 g
Resazurin solution (11 mg/44 ml)	4.0 ml
Colistin methane sulfonate	10.0 mg
Nalidixic acid	15.0 mg

Dilute up to 1 liter with distilled water and boil until solids are dissolved, autoclave, and cool to 45–50°C. Aseptically add rabbit serum (20.0 ml), tinidazole (0.6 mg), and 1.2 ml of Nile blue (Eastman Kodak Company, Rochester, NY; 75% dye content, 0.5 g/10 ml).

Selective Agar Medium (Holst et al. [1984a], cited by Spiegel [1992])

Columbia agar (BD)	42.5 g
Tinidazole	1.0 mg
Colistin	10.0 mg
Nalidixic acid	15.0 mg

Dilute up to 1 liter with distilled water and autoclave.

METHODS FOR DIRECT DETECTION OF *MOBILUNCUS* SPECIES IN CLINICAL SPECIMENS Gram-stained smears of vaginal discharge or other clinical materials and wet mounts of vaginal fluids may allow the microscopic detection of Gram-labile to Gram-negative curved rods or of motile curved rods, respectively (Teo et al., 1987). However, recognition of these structures highly depends on their concentration, the amount of other microbes present, and the epithelial or blood cell content of the specimen. Furthermore, the presence of Gram-negative and motile curved rods does not suffice to identify them as members of the genus *Mobiluncus*.

High specificity in detecting mobilunci microscopically may be achieved, however, when immunofluorescence procedures are applied. Pålsson et al. (1986a) used species-specific monoclonal antibodies and an indirect immunofluorescence test to detect and identify *Mobiluncus* species in vaginal specimens with considerable success, although they noted that two atypical strains of *M. curtisii* were not detected with their set of antibodies. Similar results were reported by Fohn et al. (1988), who employed species-, subspecies-, and genus-specific monoclonal antibodies for direct detection of *Mobiluncus* species in clinical specimens by indirect immunofluorescence. Comparably specific monoclonal antibodies were also produced by Ison et al. (1989). Polyclonal antibodies exhibited varying specificity depending on the type of antigen (untreated whole cells versus heated whole cells) used for immunization (Moi and Danielsson [1984], cited by Spiegel [1992]).

Nucleic acid probes and PCR-based techniques were also successfully used for identifying and directly detecting *Mobiluncus* species. Roberts et al. (1984), applying ³²P-labeled or biotinylated DNA and a filter blot method, were able to identify *Mobiluncus* strains to species but not subspecies level. The same probes detected mobilunci in 60–70% of specimens that were culture-positive. In a more detailed comparative study (Roberts et al., 1985b) of vaginal secretions analyzed by culture and DNA-probing, cultivation was found to be more sensitive (77%) than DNA-probe hybridization, although the sensitivity of culture appeared to be especially high in this study. However, detection by probe hybridization was considerably faster than by cultivation, being comparable with Gram stain, which of course does not allow speciation.

A hybridization assay using a ³²P-labeled synthetic oligonucleotide probe complementary to a nucleotide sequence in the variable region V8 of the *Mobiluncus* 16S rRNA (Pålsson et al., 1992) was reported to be sensitive and to react with 62 of 68 tested typical or atypical *Mobiluncus* strains. The specificity was high so that reactions

with related organisms such as *Actinomyces* species were not observed. An advantage of this test appeared to be that rRNA was used as target molecule, which may be present in copy numbers as high as 10^4 . A particularly high sensitivity was found for a PCR-based technique (Schwebke and Lawing, 2001) applied to vaginal fluids. Using this technique, 84.5% of women with BV and 38% of women without this condition gave positive results, with apparent species differences between these two groups.

Identification

Apart from the nucleic acid methodologies and serological methods briefly mentioned above, identification of *Mobiluncus* species is traditionally based upon phenotypic characteristics.

MORPHOLOGICAL AND CHEMOTAXONOMIC MARKERS In view of the unique cellular morphology of these organisms, simple microscopic techniques often suffice for detection and preliminary identification. In Gram-stained smears, the curved rods representing mobiluncii may appear Gram-positive, Gram-variable, or Gram-negative depending on the cell age (Hammann et al., 1984), the staining method (Sprott et al., 1982), or the medium from which cells were derived (Moore, 1954), but motility and anaerobic growth are stable additional properties indicative of a *Mobiluncus* strain. The active motility of *Mobiluncus* isolates may be assessed microscopically in addition, *M. curtisii* subsp. *curtisii* was reported to be able to migrate through soft agar (unlike *M. curtisii* subsp. *holmesii*), so that it thereby can be differentiated from *M. curtisii* subsp. *holmesii* (Spiegel and Roberts, 1984a; Table 16).

The cell size is an additional morphological character that differentiates between the two proposed subspecies of *M. curtisii* on the one hand and *M. mulieris* on the other hand (Curtis, 1913; Moore, 1954; Durieux and Dublanchet, 1980; Durieux and Dublanchet, 1981; Pålson et al., 1983; Spiegel et al., 1983b; Hammann et al., 1984; Spiegel and Roberts, 1984a). The smaller form measures 0.8–3 µm in length with a mean length of 1.7 µm, is only slightly bent, may appear coryneform, is more likely to stain Gram-variable to Gram-positive, and usually represents *M. curtisii* (Fig. 34). The larger form (1.9–6.0 µm in length; mean length 2.9 µm) appears moon-like and may even form a half circle, almost invariably appears Gram-negative, and generally represents *M. mulieris* (Table 16; Fig. 35). Colonies are colorless, translucent, smooth, slightly convex, and entire; they reach a maximum diameter of 2–3 mm after 5 days of incubation (Fig. 36).

The pattern of cellular fatty acids (see the section on Chemotaxonomy in this Chapter) may also aid in the recognition of the genus.

PHYSIOLOGICAL CHARACTERISTICS The determination of the metabolic end products from growth of mobiluncii in peptone yeast extract glucose medium (PYG) helps to separate *Mobiluncus* species from other curved bacteria and to relate them to the family Actinomycetaceae, the major end products being succinic, acetic and lactic acids (Hjelm et al., 1982; Holst et al., 1982; Hammann et al., 1984; Spiegel and Roberts, 1984a; Vetere et al., 1987; Table 16).

Various methods and commercial systems have been used to assess the fermentative degradation of carbohydrates and the enzymatic activity of *Mobiluncus* strains. These include the Minitek® system (Becton-Dickinson; Hjelm et al., 1982; Pålson et al., 1983), prereduced anaerobically sterilized media with and without added serum (Holst et al., 1982; Spiegel and Roberts, 1984a), the Rapid ID 32A system (Pattyn et al., 1993), and the Crystal anaerobe identification system (Becton-Dickinson; Cavallaro et al., 1997). The results obtained by these methods and systems differed to a considerable extent, and some commercial systems were not able to distinguish between subspecies and even species. These uncertainties also apply to the results of enzyme activity tests as obtained by the API ZYM (bioMérieux) or combined systems of this manufacturer that include enzyme tests (Holst et al., 1982; Pålson et al., 1983; Spiegel and Roberts, 1984a).

Nevertheless, it appears appropriate to select certain carbohydrate fermentation and enzyme tests (Table 16) that are obviously suitable for identifying and differentiating *Mobiluncus* species and subspecies. When supplemented with morphological and growth characteristics, they clearly provide an acceptable level of diagnostic reliability.

SEROLOGICAL IDENTIFICATION AND SEROLOGICAL DIAGNOSIS OF MOBILUNCUS INFECTIONS AS *M. curtisii* and *M. mulieris* were shown to differ clearly in their respective antigenic compositions (Roberts et al., 1985a), serological methods may be used not only for direct detection in clinical specimens but also for identification from culture. Monoclonal antibodies have especially been used for this purpose, immunofluorescence being a simple and reliable but somewhat expensive technique because of personnel costs (Fohn et al., 1988). Furthermore, it should be kept in mind that antigenically atypical variants occur so that especially highly specific monoclonal antibodies may misidentify some isolates (Pålson

et al., 1986a). Two of these atypical groups of isolates were characterized by Schwebke et al. (1991) biochemically, antigenetically, morphologically as well as by DNA hybridization, and one of them was found to belong to *M. mulieris* and the other one to *M. curtisii*. Gatti et al. (1997), in a study of 30 vaginal *Mobiluncus* isolates (22 *M. curtisii* and 8 *M. mulieris*), identified two antigenic profiles within *M. curtisii* and some antigenic variability within *M. mulieris* using immunoblotting but were still able to identify mobiluncal at the species level.

Schwebke et al. (1996), also using immunofluorescence techniques, studied the prevalence of antibodies to *M. curtisii* in pregnant women, pediatric patients, and sexually inexperienced women. In these three groups, the immunoglobulin G antibody prevalence was 75, 6, and 0%, respectively. This was interpreted as an indication that serum antibodies could possibly be used as a diagnostic marker for BV.

Epidemiology

The etiological role of *Mobiluncus* species in the pathological lesions from which they have been recovered remains to be elucidated in detail. However, numerous reports leave no doubt that these organisms show a striking although not obligate association with a condition commonly termed bacterial vaginosis (BV). This condition is defined as a characteristic change in the vaginal flora from lactobacilli to strict and facultative anaerobes, among which *Gardnerella vaginalis*, *Mycoplasma hominis*, certain Bacteroidaceae and *Mobiluncus* spp. are most prominent (Mårdh, 1993).

Studies on the epidemiology of BV from the United States, Serbia, Spain, Italy, Sweden, Thailand and Japan showed some differences in the incidence of this condition in relation to the clinical background of the women examined, sexual activity, and race and ethnicity. Georgijevic et al. (2000) reported an average incidence of 10–35% in women visiting gynecological wards, 10–30% in patients visiting obstetric wards, and 20–60% in women visiting facilities that serve those affected by sexually transmitted diseases. More than 50% of these women were asymptomatic. Risk factors for acquiring BV in this study were reported to be multiple sexual partners, exposure to semen, previous trichomoniasis, use of intrauterine contraceptive devices, smoking, indigence, and frequent use of scented soap (Georgijevic et al., 2000).

In a pregnant population of Barcelona, Spain, the incidence of BV was 7.5% (Martinez de Tejada et al., 1998). No correlation between race, parity, education, marital status, smoking, or

drug use and BV could be demonstrated in this study. However, a significant association of BV was observed with non-use of birth control methods, presence of sexually transmitted diseases during pregnancy, and HIV seropositivity. Comparing Japanese and Thai pregnant women, Puapermpoonsiri et al. (1996) found a prevalence of BV of 13.6% and 15.9%, respectively. In an Italian population of asymptomatic pregnant women, the incidence of BV was reported to be 4.9% (Cristiano et al., 1996). Holst et al. (1994) were able to correlate the presence of BV with obstetrical problems: BV was diagnosed in 41% of women who had both preterm labor and preterm delivery, while the incidence of the condition was 11% in women who had preterm labor but term delivery and also in women who had both term labor and delivery.

Royce et al. (1999), studying the relationship of BV during pregnancy and black race and ethnicity, demonstrated significant differences between black and white women (22.3% vs. 8.5%). Adjustment for sociodemographics, sexual activity, sexually transmitted diseases, health behavior, and sexual hygiene did not explain these differences. In an attempt to relate these differences to known risk factors, Ness et al. (2003) enrolled 900 black and 235 white women in a study from five United States sites. The results of this study confirmed that black women were more likely than white women to have BV. Furthermore, black women were also more likely to be older, have lower educational attainment and family incomes, and have a history of sexually transmitted diseases. However, after adjustment for demographic and lifestyle factors, blacks remained at elevated risk for BV, so that the observed racial disparity in the occurrence of BV could not be explained by risk factor differences.

Although there is a significant correlation between BV and the presence of *Mobiluncus* species in vaginal secretions, these organisms are not always present when BV is diagnosed (84.5% according to Schwebke and Lawing, 2001), and they may be recovered in up to 38% of women without signs of BV (Schwebke and Lawing, 2001). Also Kaneko et al. (1992), investigating the occurrence of *Mobiluncus* species in Japanese women, found a significant difference between patients with BV and clinically healthy pregnant and nonpregnant women (27.3% vs. 0.7–3.2%). In women attending a sexually transmitted disease clinic, the detection rate of mobiluncal was 53% of those with and 4% of those without BV (Hillier et al., 1991).

As far as extragenital *Mobiluncus* infections are concerned, epidemiological conclusions cannot be drawn owing to the rare and sporadic occurrence of these conditions.

Pathogenicity

BACTERIAL VAGINOSIS Despite the unambiguous association of BV and the presence of *Mobiluncus* species in vaginal fluids, the etiological role of these organisms in the pathogenesis of this condition is difficult to assess definitively. The reasons for this difficulty are 1) mobiluncii have never been recovered in pure culture from vaginal discharge but rather in combination with various other microbes, and 2) mobiluncii may be encountered without clinical or bacteriological signs of disease or impairment. However, this is a problem characteristic of all of the indigenous, facultatively pathogenic microbes etiologically involved in human or animal disease and particularly applies to facultative or strict anaerobes including most members of the family Actinomycetaceae. The observation that differences in the severity of BV between women with or without *Mobiluncus* species or in their response to treatment (Spiegel et al., 1983; Jones et al., 1985) cannot be demonstrated does not exclude the pathogenic potential of the organisms, as this is also true for several other anaerobic species that predominantly or exclusively occur in synergistic mixed infections.

Bacteria Potentially Involved in the Etiology of Bacterial Vaginosis The typical bacterial flora associated with clinical signs of BV consists of *Prevotella bivia*, *Prevotella disiens*, *Porphyromonas* spp., *Mobiluncus* spp., anaerobic streptococci, and *Mycoplasma hominis* (Spiegel, 1991; Kimberlin and Andrews, 1998). Both the exact species composition and their relative concentrations vary among women having this condition, indicating that etiology and pathogenesis of BV are comparable to that of other polymicrobial infections, especially to those of endogenous origin.

More detailed analyses of the prevalence of the two *Mobiluncus* species in patients with BV revealed that *M. curtisii* appears to be significantly more often associated with this condition than *M. mulieris*. Schwebke and Lawing (2001), using a PCR-based procedure, reported that *M. curtisii* was rarely detected in women without signs of BV; in contrast, this species was identified in 65.3% of the patients suffering from BV. Moi et al. (1991), using an indirect immunofluorescence assay, demonstrated significantly higher titers of IgG antibodies to *M. curtisii* ($p < 0.01$) than to *M. mulieris* in women with BV. Furthermore, these titers were higher in patients with BV than in women without this condition and in healthy males. No secretory IgA antibodies to *Mobiluncus* species were found in vaginal washings.

Potential Virulence Factors of Mobiluncus spp. Using luminol-enhanced chemiluminescence, *M.*

curtisii was shown to induce a significantly less pronounced oxidative metabolism of polymorphonuclear leukocytes than that of *M. mulieris*, indicating that the former species is apparently able to escape phagocytosis more easily. In light of these findings, the earlier report of DeBoer and Plantema (1988), who saw curved rods inside phagocytic vacuoles of vaginal polymorphonuclear leukocytes, could mean that the intraphagocytic organisms were *M. mulieris* rather than *M. curtisii*. The same authors, investigating the *in situ* adherence of *Mobiluncus* to detached vaginal epithelial cells by electron microscopy, found that the curved rods attached both directly to the epithelial cell surface and at various distances from it. From this finding, they concluded that after initial adherence the motile bacteria were able to grow on the epithelial surface in sessile microcolonies. This ability appeared to be due to the inclusion in a matrix of exopolysaccharides, and the production of such a glycocalyx could be demonstrated *in vitro* for both *M. curtisii* subsp. *curtisii* and *M. mulieris*.

Both *Mobiluncus* species were shown to produce a cytotoxin active against Vero cells and four other cell lines (Taylor-Robinson et al., 1993). The marked cytopathic effect led to destruction of the cells within 72 h. In bovine oviduct organ cultures, eight *M. curtisii* and two *M. mulieris* strains caused loss of ciliary activity, which was complete after 60 h. Histologic changes were also observed. The toxin was identified to be extracellular and relatively heat-stable; at pH 9 and pH 3, it lost its activity.

Ecological Aspects of Alterations of the Vaginal Flora There is no doubt that these potential virulence factors do not suffice to explain the development of BV, especially because *Mobiluncus* species cannot be detected in all of the patients exhibiting clinical symptoms of the condition. The most obvious finding characteristic of all cases of BV is the typical alteration of the vaginal flora, which can be demonstrated microscopically, culturally, or by molecular techniques. This alteration of the vaginal flora consists of a dramatic decrease in numbers of indigenous lactobacilli and replacement of these bacteria by *Prevotella* spp., *Porphyromonas* spp., *Gardnerella vaginalis*, *Mycoplasma hominis* and *Mobiluncus* spp. (Goldacre et al., 1979; Spiegel et al., 1980; Taylor et al., 1982; Blackwell et al., 1983; Rabe et al., 1988).

As a result of these changes in the vaginal ecosystem, various alterations of the vaginal milieu occur that can be related to activities of the above-specified mixed facultative and anaerobic flora. The absence of *Lactobacillus* species has two major consequences: Lactic acid concentration due to these bacteria is decreased in the

vaginal fluid, facilitating elevated pH values, and the antagonistic effect of hydrogen peroxide on nonphysiological microbes is missing (Skarin and Sylwan, 1986; Spiegel, 1991). In a detailed study, Nagy et al. (1991) found that 79% (n = 47) of *Lactobacillus* strains derived from women without BV produced H₂O₂, while only 23% (n = 39) of the isolates from patients with BV did so. Five of 20 H₂O₂-producing and two of 26 non-producing strains exhibited inhibitory activities against four of 12 strains of anaerobic streptococci and two of 10 *Mobiluncus* isolates. None of another 41 different anaerobic and facultatively anaerobic bacterial strains was inhibited by any of the *Lactobacillus* isolates tested. Increasing the iron content of the medium by adding FeCl₃ (0.01–1 mM) decreased or completely abolished the antibiosis.

Several authors have demonstrated that metabolic or enzymatic activities of the altered vaginal flora of BV patients directly contribute to the development of the condition. Gonzales Pedraza Aviles et al. (1999) related the production of aminopeptidases and decarboxylases by anaerobes of the BV flora to the conversion of protein and amino acids to amines that are responsible for raising the vaginal pH and producing the typical odor of the vaginal discharge characteristic of the syndrome. The biological activity of the fermentation end products of vaginal anaerobes also has attracted attention. Sturm (1989a) as well as Al-Mushrif et al. (2000) studied the role of succinic acid on the chemotactic response of white blood cells. Sturm (1989) observed that certain succinate-producing anaerobes including mobilunci inhibited the chemotactic response of granulocytes while "*Peptostreptococcus productus*" (*Ruminococcus productus*) and *Escherichia coli* did not. Al-Mushrif et al. (2000) exposed a monocytic cell line (MonoMac 6) to varying concentrations of pure succinic, acetic and lactic acids. In this model, succinic acid exhibited high inhibition of chemotaxis; lower inhibition and no inhibition were observed with acetic and lactic acids, respectively. Correspondingly, succinic and acetic acids were detected in high concentrations in the vaginal fluids of patients with BV, and these fluids but not those of healthy women had the same inhibitory effect on the monocytic cell line.

Complications of Bacterial Vaginosis The importance of BV as a disease rather than a mere imbalance of the vaginal microflora is underlined by numerous observations of various types of complications associated with BV. Vaginal bleeding has been reported in women with BV although *Mobiluncus* spp. were not recovered from all of them (Larsson and Bergman, 1986). Especially well documented is an association of

BV late in pregnancy with an increased risk of developing chorioamnionitis, premature labor, and preterm delivery (Hillier et al., 1988; Martius et al., 1988; McGregor et al., 1994). Mucinas and sialidases produced by BV bacteria were thought to contribute to the development of these adverse pregnancy outcomes. McGregor et al. (1994) not only could confirm that presence of BV in pregnant women at intake was associated with increased risk of preterm birth, premature rupture of membranes, and preterm premature rupture of membranes, but also found that mucinase and sialidase activities were more commonly encountered in these women and that these enzymes occurred in higher concentrations. Furthermore, a treatment study with 2% clindamycin vaginal cream revealed that persistence of sialidase-producing organisms in numbers sufficient to increase vaginal fluid sialidase activity obviously was a risk factor for possibly preventable subclinical intrauterine infection and preterm birth. Sialidase activity was found to be associated with *Gardnerella vaginalis*, *Mobiluncus* spp., *Mycoplasma hominis* as well as *Chlamydia trachomatis* and yeasts; mucinase activity was only detected with BV-linked organisms (McGregor et al., 1994).

Additional complications and sequelae reported in conjunction with BV are cervicitis, salpingitis, endometritis, pelvic infections, post-operative infections, and even urinary tract infections (Georgijevic et al., 2000), although Pattman reported that signs of ascending infections or urinary tract symptoms were not more common in BV patients with and without *Mobiluncus* species (Pattman [1984], cited in Spiegel [1992]).

EXTRAGENITAL MOBILUNCUS INFECTIONS

Extragenital infections due to *Mobiluncus* species have increasingly been reported. In particular, these were nonpuerperal breast abscesses in females (Glupeczynski et al., 1984; Sturm and Sikkenk, 1984; Weinbren et al., 1986; Bennett et al., 1989; Edmiston et al., 1989; Sturm, 1989b; Sota et al., 1993) and in a male (Sturm, 1989b). Sturm (1989b) analyzed 109 specimens from nonpuerperal breast masses and found anaerobes or mixed infections in 43% of them. Seven (16%) of 44 samples containing anaerobes also yielded growth of *Mobiluncus* spp., of which six were identified as *M. curtisii* and one as *M. mulieris*. The author concluded that the development of these abscesses might be related to sexual activity. The one nonpuerperal breast abscess reported by Edmiston et al. (1989) was attributed to *M. curtisii* subsp. *holmesii*.

Other extragenital localized lesions assigned to mobilunci were an abdominal abscess (Mayer et al., 1994), a mixed-infected suppurative of the

naval, and an exudative postoperative wound infection after radical mastectomy (Glupczynski et al., 1984). Furthermore, bacteremia due to *M. curtisii* following septic abortion (Gomez-Garces et al., 1994) and a severe sepsis due to *M. curtisii* subsp. *curtisii* (Hill et al., 1998) were observed. In the latter case, the generalizing infection became life threatening by causing septic shock, renal failure, disseminated intravascular coagulation, adult respiratory distress syndrome, and spontaneous splenic rupture. Despite these serious complications, the 54-year-old female patient survived with full intensive care support and intravenous application of ceftriaxone.

TREATMENT OF *MOBILUNCUS* INFECTIONS AND ANTIMICROBIAL SUSCEPTIBILITY Treatment of bacterial vaginosis has been attempted using local application of clindamycin phosphate cream or oral metronidazole, erythromycin, or ofloxacin (Nygaard et al., 1991; Nagayam et al., 1992; Wathne et al., 1993; McGregor et al., 1994; Mikamo et al., 1996; Porozhanova and Bozhinova, 2000). Good therapeutic results were reported for local clindamycin cream as well as for oral metronidazole, the former being possibly slightly more effective (Mikamo et al., 1996). Erythromycin appeared to be clearly less effective than metronidazole (Wathne et al., 1993); the same is true for ofloxacin although some efficacy of this drug was observed (Nagayam et al., 1997).

Susceptibility tests of *Mobiluncus* spp. revealed good in vitro activities of clindamycin, imipenem, cefmetazole, amoxicillin, and amoxicillin plus clavulanic acid (Puapermpoonsiri et al., 1997). However, metronidazole was found to be ineffective, which had already been reported by Spiegel (1992) for *M. curtisii* and some strains of *M. mulieris*. Rifaximin, a new topical rifamycin derivative, also showed very good in vitro activity against mobilunci (Hoover et al., 1993). Among many other human bacterial isolates, also *M. curtisii* carried the tetracycline resistance determinant *tetQ*, which was found to be integrated into the chromosome (Leng et al., 1997). In contrast to gene transfer from other anaerobes possessing *tetQ*, transfer of this gene from one *M. curtisii* strain into an *Enterococcus faecalis* recipient failed.

In view of the difficulties encountered when cultivating mobilunci, Croco et al. (1994) compared the E-test with standard procedures for susceptibility testing and found that the results for *Mobiluncus* isolates correlated well with those of the standard technique used.

The Family Streptomycetaceae, Part I: Taxonomy

PETER KÄMPFER

Phylogeny and Taxonomy

The family Streptomycetaceae was created by Waksman and Henrici (1943). Originally this family harbored only the type genus *Streptomyces*. Zhang et al. (1997) proposed that the genus *Kitasatospora* be included, and recently, a third genus, *Streptacidiphilus*, was added (Kim et al., 2003).

Description of the family Streptomycetaceae Waksman and Henrici 1943 emend, Kim et al. (2003) (Strep.to.my.ce.ta'ce.ae. ending to denote a family; M.L. masc. n. *Streptomyces*, type genus of the family) is based on data taken from Williams et al. (1989), Zhang et al. (1997) and Kim et al. (2003). These aerobic, Gram-positive, non-acid-alcohol fast actinomycetes form an extensively branched substrate mycelium that rarely fragments. The aerial mycelium forms chains of three to many spores. Members of a few species bear short chains of spores on the substrate mycelium. The organisms produce a wide range of pigments responsible for the color of the substrate and aerial mycelium. The organisms grow within different pH ranges, namely 5.5–9 (*Kitasatospora*), 5–11.5 (*Streptomyces*), and 3.5–6.0 (*Streptacidiphilus*). They are chemoorganotrophic with an oxidative type of metabolism. The substrate mycelium contains either LL- (*Streptacidiphilus* and *Streptomyces*) or meso- (*Kitasatospora*) diaminopimelic acid as the predominant diamino acid; aerial or submerged spores contain LL-diaminopimelic acid. In whole-organism sugar profiles, either major amounts of galactose or galactose and rhamnose (*Kitasatospora* and *Streptacidiphilus*) can be detected. Lipid profiles typically contain hexa- and octa-hydrogenated menaquinones with nine isoprene units as the predominant isoprenologues. The polar lipid profiles are composed of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. Fatty acids are complex mixtures of saturated, *iso*- and *anteiso*-fatty acids. Mycolic acids are not present. The mol% G + C of the DNA ranges generally between 66 and 74%. Members of all three taxa are widely distributed in terrestrial habitats, especially soil.

Very few species are pathogens for animals (including man) and plants.

A phylogenetic tree showing selected representatives of all three genera (all species of *Streptacidiphilus* and *Kitasatospora* and selected *Streptomyces* “species”) representing the clusters of the numerical taxonomic study of Williams et al. (1983a) is shown in Fig. 1. The genera are difficult to differentiate on the basis of phenotypic features (including chemotaxonomic markers). Some characteristic features are shown in Table 1.

History

Early investigations of actinomycetes, including streptomycetes, were dominated by a strong emphasis of morphology and the high degree of morphological diversity was subsequently considered to be sufficient for their assignment to genera and families (Waksman, 1961; Cross and Goodfellow, 1973). A short summary of early classification systems of actinomycetes is given in Introduction to the Classification of the Actinomycetes in this Volume. Streptomycetes are the producers of more than 5000 known bioactive compounds (Anderson and Wellington, 2001), and estimates of the total number of antimicrobial compounds produced by representatives of *Streptomyces* screened for new antibiotics are of the order of 100,000 (Watve et al., 2001). In addition, not only has the overall versatility of these compounds been studied in great detail, but also a high proportion of them have known biological effects, which is unparalleled in the living world (Kieser et al., 2000).

The family Streptomycetaceae was originally proposed by Waksman and Henrici (1943) and contained at that time only two genera: the genus *Streptomyces* and the genus *Micromonospora*. *Streptomyces* was described as “Streptomycetaceae,” forming spores in chains on aerial hyphae. Spores are apparently endogeneous in origin, formed by a segregation of protoplasm within the hyphae into a series of round oval or cylindrical bodies. Chains of spores are often spirally coiled. Sporophores may be simple or branched (Waksman and Henrici, 1943). Figure 2 shows the morphology of the aerial mycelium of

Fig. 1. Phylogenetic analysis based on 16S rRNA gene sequences available from the European Molecular Biology Laboratory data library (accession numbers are given in brackets) constructed after multiple alignment of data. Calculations of distances (distance options according to the Kimura-2 model) and clustering with maximum parsimony method were performed using the software package Mega (Molecular Evolutionary Genetics Analysis) version 2.1. Bootstrap values based on 1000 replications are listed as percentages at the branching points.

three streptomycetes. Although they are important (see Table 2 of The Family Nocardiopsaceae in this Volume), morphological differences between members of the actinomycete genera do not represent the extensive diversity of genera and species of the sporoactinomycetes.

Beginning in the 1950s, new developments in the application of numerical phenetics, numerical taxonomy, chemosystematics, and finally molecular systematics revolutionized the classification of actinomycetes. These developments

have been excellently reviewed for actinomycete systematics by Goodfellow et al. (1999).

The determination of major cell wall sugars and peptidoglycan composition (Lechevalier and Lechevalier, 1970; Schleifer and Kandler, 1972) led to a classification system of well-characterized chemotypes and peptidoglycan types. The pioneering work of Lechevalier and coworkers (Becker et al., 1964; Lechevalier and Lechevalier, 1970) clearly showed that *Streptomyces* and the other genera of the family Strep-

Table 1. Chemotaxonomic, morphological and physiological characteristics of *Kitasatospora*, *Streptacidiphilus* and *Streptomyces* strains.

Characteristics	<i>Streptomyces</i>	<i>Kitasatospora</i>	<i>Streptacidiphilus</i>
Long chains of spores formed on aerial hyphae	+	+	+
Major menaquinones	MK-9(H ₆ , H ₈)	MK-9(H ₆ , H ₈)	MK-9(H ₆ , H ₈)
Predominant phospholipids	DPG, PE, PI, and PIMs	DPG, PE, PI, and PIMs	DPG, PE, PI, and PIMs
Diagnostic sugars in whole-organism hydrolysates	None	Galactose ^a	Galactose and rhamnose
Fatty acid pattern ^d	2c	2c	2c
G+C content of DNA (mol %)	66–73	70–74	70–72
Isomer(s) of diaminopimelic acids in whole-organism hydrolysates	LL-A _{2pm}	LL-/meso-A _{2pm} ^b	LL-A _{2pm}
Optimal pH range	6.5–8.0 ^c	ND	4.5–5.5
pH range for growth	5.0–11.5	5.5–9.0	3.5–6.0

Symbols and abbreviations: +, present; 2c, fatty acid group *sensu* Kroppenstedt (1985); DPG, diphosphatidylglycerol; PE, phosphatidylethanol; PI, phosphatidylinositol; PIMs, phosphatidylinositol mannosides; MK-9(H₆, H₈), hexa- and octa-hydrogenated menaquinones with nine isoprene units; and ND, not determined.

^aRhamnose was detected in whole-organism hydrolysates of *Kitasatospora mediocidica* (Labeda, 1988).

^bAerial and submerged spores contain LL-A_{2pm} and vegetative mycelia meso-A_{2pm}.

^cAlkalophilic strains, which grow between pH 8.0 and 11.5, have an optimum at pH 9–9.5 (Mikami et al., 1982).

From Kim et al. (2003) and the previous studies of Shirling and Gottlieb (1976), Ōmura et al. (1989), Lonsdale (1985), Williams et al. (1989) and Nakagaito et al. (1992).

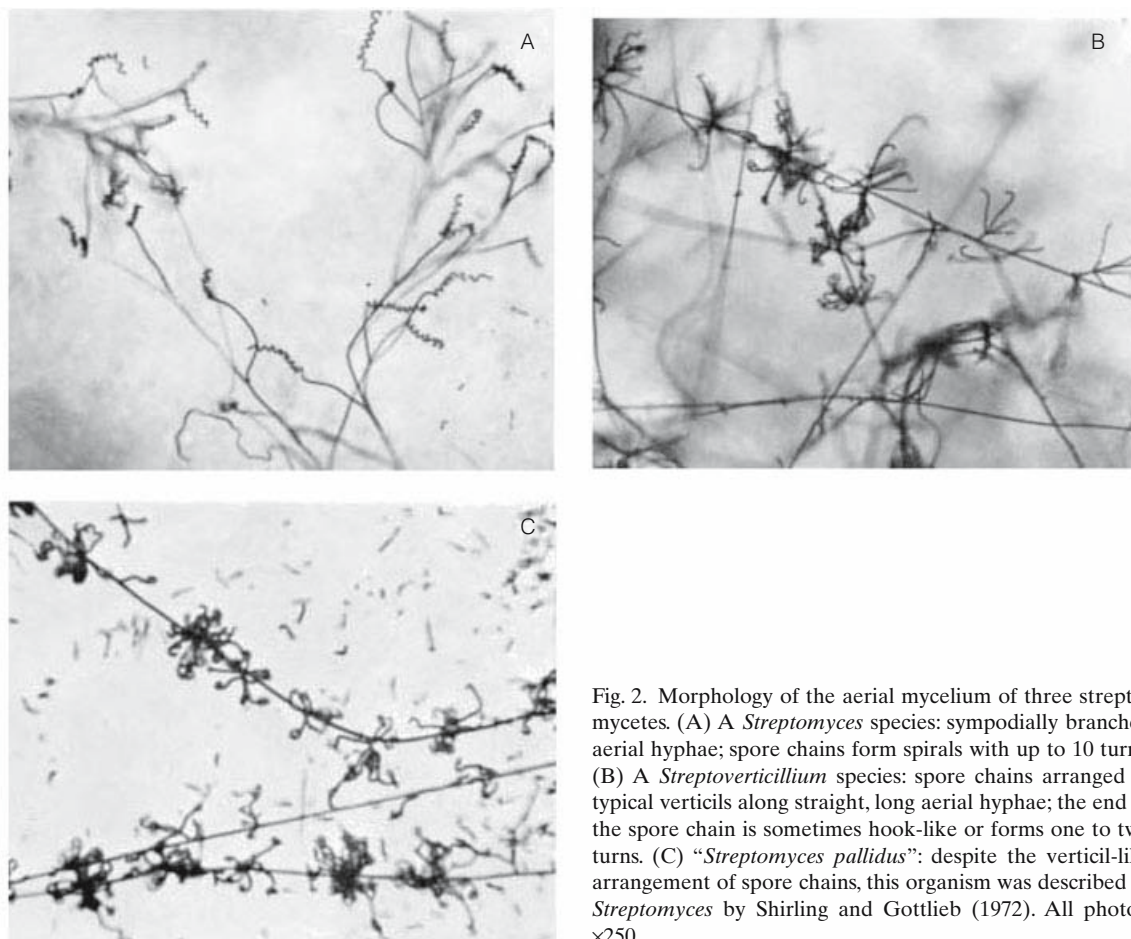

Fig. 2. Morphology of the aerial mycelium of three streptomycetes. (A) A *Streptomyces* species: sympodially branched aerial hyphae; spore chains form spirals with up to 10 turns. (B) A *Streptoverticillium* species: spore chains arranged in typical verticils along straight, long aerial hyphae; the end of the spore chain is sometimes hook-like or forms one to two turns. (C) “*Streptomyces pallidus*”: despite the verticil-like arrangement of spore chains, this organism was described as *Streptomyces* by Shirling and Gottlieb (1972). All photos: $\times 250$.

Table 2. Key biochemical markers of Streptomycetaceae genera and some other selected actinomycete genera (belonging to different families) producing an aerial mycelium.^a

Family and genus	Diaminopimelic acid (A _{2pm}) ^b	Glycine in IPB ^b	Peptidoglycan type ^b	Sugar type ^b	Phospholipid type ^c	Mycolic acids ^b	Fatty acid pattern ^d	Menaquinones ^e	G+C content (mol%)

ⁱData from R. Kroppenstedt (personal communication).

^jData for menaquinones from Howarth et al. (1986).

Modified according to Korn-Wendisch and Kutzner (1992).

tomycetaceae, proposed by then, contained LL-diaminopimelic acid (LL-A₂pm) in its peptidoglycan (cell wall type I), whereas *meso*-A₂pm was found in most of the other actinomycetes described at that time. The genera containing LL-A₂pm in their peptidoglycan contained an interpeptide bridge composed of a glycine residue (type A3γ of Schleifer and Kandler, 1972). In addition to these chemical traits, which had the advantage of higher genetic stability in comparison with morphological features, the pattern of sugars in whole-cell hydrolysates (Lechevalier and Lechevalier, 1970), phospholipids (Lechevalier et al., 1977a), fatty acids (Kroppenstedt, 1985), menaquinones (Alderson et al., 1985; Kroppenstedt, 1985), and acetylated muramic acid residues (Uchida and Aida, 1977) were shown to be of essential importance for the classification of actinomycetes. Major chemotaxonomic markers of the genus *Streptomyces* and other actinomycete genera are given in Table 2. In combination with other phenotypic properties, like physiological and biochemical characteristics, these traits were also helpful in defining genera within the family Streptomycetaceae. This resulted in the reclassification of six additional genera (*Actinopycnidium*, *Actinosporangium*, *Chainia*, *Elytrosporangium*, *Kitasatoa* and *Microellobosporia*), described mainly on the basis of morphological features, to the genus *Streptomyces* (Williams et al., 1983a; Goodfellow et al., 1986b; Goodfellow et al., 1986c; Goodfellow et al., 1986d; Goodfellow et al., 1986e).

The application of 16S rRNA oligonucleotide cataloguing (Stackebrandt and Woese, 1981) and subsequently the sequencing of the 16S rRNA genes provided a basis for studies of the natural relationships among actinomycetes and related organisms (for details, see Stackebrandt et al., [1997] and Introduction to the Classification of the Actinomyces in this Volume). On the basis of these data, the description of the family Streptomycetaceae was emended by Wellington et al. (1992) and Witt and Stackebrandt (1990), who proposed the unification of the genera *Kitasatospora* and *Streptoverticillium* with the genus *Streptomyces*, and more recently by Stackebrandt et al. (1997), who excluded the genus *Sporichthya*. Zhang et al. (1997) demonstrated, however, that the genus *Kitasatospora* formed a stable subbranch in *Streptomyces*, when sequences from the almost complete 16S rRNA genes were compared. In addition, members of the genus *Kitasatospora* can be distinguished from *Streptomyces* by the ratio of *meso*-DAP to LL-DAP and the presence of galactose in whole-cell hydrolysates (Zhang et al., 1997; Table 1). The genera *Kineosporia* and *Sporichthya*, both sharing chemotaxonomic similarities with members of the genus *Streptomyces* and considered

to be members of this genus (Logan, 1994), have been shown by 16S rRNA sequencing to be independent genera: *Sporichthya* is a member of the family Sporichthyaceae of the suborder Frankineae (Stackebrandt et al., 1997), and the genus *Kineosporia* is grouped together with *Kineococcus* (Kudo et al., 1998) into the tentative family "Kineococcaceae" (see Introduction to the Classification of the Actinomyces in this Volume). Recently the genus *Streptacidiphilus* has been proposed by Kim et al. (2003) to accommodate acidophilic actinomycetes forming a distinct clade within the family Streptomycetaceae.

Note that although 16S rRNA sequence analyses have provided a framework for prokaryotic classification, the current classification system based on this molecule has not yet solved the taxonomic problems within the genera (especially within the genus *Streptomyces*). Several studies have attempted to use sequence data from variable regions of 16S rRNA to establish taxonomic structure within the genus, but the variation is too limited to resolve problems of species differentiation (see Witt and Stackebrandt [1990], Stackebrandt et al., [1991], Stackebrandt et al., [1992], Anderson and Wellington [2001], and the references therein).

The discovery of antibiotics produced by streptomycetes in the 1940s, which led to extensive screening for novel bioactive compounds, and the subsequent need for patenting, which led to an extreme overclassification of the genus, complicated the situation. Producers of novel natural products were described as new species and patented. Species described within the genus *Streptomyces* increased from approximately 40 to over 3000 (Trejo, 1970). The current status of streptomycete taxonomy including phylogeny has been summarized by Anderson and Wellington (2001) and will be treated briefly in the next sections. Of the 539 species and subspecies listed under the List of Bacterial Names with Standing in Nomenclature as of December 9, 2003, 376 are on the Approved lists (Tables 3 and 4).

Genus *Kitasatospora*

Zhang et al. (1997) revived the genus *Kitasatospora* to accommodate actinomycete strains forming a stable, separate subbranch on the basis of phylogenetic analyses within the family Streptomycetaceae and containing major amounts of *meso*-DAP in their whole-cell hydrolysates. Phylogenetic trees were also constructed by using 16S-23S rRNA gene spacers, leading to groupings similar to those based on 16S rRNA sequence data (Zhang et al., 1997).

The substrate mycelium of members of *Kitasatospora* is as well developed as the *Streptomy-*

Table 3. Studies on numerical classification of streptomycetes.

Abbreviation: ISP, International *Streptomyces* Project.

^aFourteen and 168 were obtained by the Wrocław taxonomy method (dendrite method); 21 and 37 were obtained by the centrifugal correlation method. Modified according to Korn-Wendisch and Kutzner (1992).

ces substrate mycelium. The aerial mycelium bears long spore chains with more than 20 spores. Galactose is present in whole-cell hydrolysates of *Kitasatospora*. Specific nucleotide signatures in the sequences of both 16S rRNA and 16S-23S rRNA gene spacers can differentiate *Kitasatospora* from *Streptomyces* (for details, see Zhang et al., 1997); however, phenotypic differences between *Streptomyces* and *Kitasatospora* are not pronounced so that the separate genus status of *Kitasatospora* may be questioned.

To date, eleven species of the genus *Kitasatospora* have been recognized: *Kitasatospora setae* (Omura et al. 1982), *Kitasatospora phosalacinea* (Takahashi et al., 1984a), *Kitasatospora griseola* (Takahashi et al., 1984a), *Kitasatospora mediocidica* (Labeda, 1988), *Kitasatospora cystarginea* (Kusakabe and Isono, 1988), *Kitasatospora cochleata* (Nakagaito et al., 1992b; Zhang et al., 1997), *Kitasatospora paracochleata* (Nakagaito et al., 1992b; Zhang et al., 1997), *Kitasatospora azatica* (Nakagaito et al., 1992b; Zhang et al., 1997), *Kitasatospora cheerisanensis* (Chung et al., 1999), *Kitasatospora cineracea* (Tajima et al., 2001) and *Kitasatospora niigatensis* (Tajima et al., 2001).

The designations of some species to this genus are open to discussion. *Kitasatospora cystarginea*, *Kitasatospora griseola*, *Kitasatospora mediocidica*, *Kitasatospora phosalacinea* and *Kitasatospora setae* are synonyms of *Streptomyces cystargineus*, *Streptomyces griseolosporus*, *Streptomyces mediocidicus*, *Streptomyces phosalacineus* and *Streptomyces setae*, respectively. For these species, and according to scientific opinion, an author may use *Kitasatospora* or *Streptomyces*. See the List of Bacterial Names with Standing in Nomenclature for detailed comments.

Genus *Streptacidophilus*

The genus *Streptacidophilus* was proposed by Kim et al. (2003) to accommodate acidophilic actinomycetes isolated from acidic soils and litter. On the basis of 16S rRNA sequence analysis, it could be shown that the 11 isolates formed a stable clade within the family Streptomycetaceae. These organisms showed a distinctive pH profile, showed a unique 16S rDNA signature, and contained major amounts of LL-diaminopimelic acid, galactose and rhamnose in whole-cell hydrolysates (Kim et al., 2003). The members of the genus form an extensively branched, nonfragmenting mycelium carrying long chains of spores in aerial mycelia at maturity (Kim et al., 2003). To date, three species have been recognized: *Streptacidophilus albus*, *Streptacidophilus neutrinimicus* and *Streptacidophilus carbonis*.

Similar to *Kitasatospora*, *Streptomyces* and *Streptacidophilus* have no pronounced phenotypic differences, so that a separate genus status also of *Streptacidophilus* may be questioned.

Genus *Streptomyces*

The genus *Streptomyces* Waksman and Henrici (1943) is the type genus of the family. Most of the general characteristics described below also apply to members of the genera *Kitasatospora* and *Streptacidophilus*, unless stated otherwise.

GENERAL CHARACTERISTICS Streptomycetes are Gram-positive aerobic members of the order Actinomycetales within the class Actinobacteria (Stackebrandt et al., 1997) and have a DNA G+C content of 69 ± 78 mol%. The vegetative hyphae (0.5–2.0 μm in diameter) produce an extensively branched mycelium that rarely fragments. The aerial mycelium at maturity forms chains of three to many spores. Some species may bear

short chains of spores on the substrate mycelium. Sclerotia, pycnidial-, sporangia-, and synnemata-like structures may be formed by some species. The spores are nonmotile. On complex agar media, discrete and lichenoid, leathery or butyrous colonies are formed. Colonies are initially relatively smooth surfaced, but later they develop an aerial mycelium that may appear floccose, granular, powdery or velvety.

Members of the genus *Streptomyces* undergo a complex life cycle, which has been studied most intensively for strain “*S. coelicolor*” A2(3). *Streptomyces* colonies are multicellular, differentiated organisms exhibiting temporal and spatial control of gene expression, morphogenesis, metabolism and the flux of metabolites (see chapter 2 of Kieser et al., [2000] for more details).

Strains belonging to the genus *Streptomyces* may produce a wide variety of pigments responsible for the color of the vegetative and aerial mycelia (Figs. 3 and 4). In addition, colored diffusible pigments may also be formed. Note that the production of pigments largely depends on the medium composition and cultivation conditions (Figs. 3 and 4). Many strains produce one or more antibiotics (more details are given in The Family Streptomycetaceae, Part II: Molecular Biology in this Volume). The metabolism is oxidative and chemoorganotrophic. The catalase reaction is positive, and generally, nitrates are reduced to nitrites. Most representatives can degrade polymeric substrates like casein, gelatin, hypoxanthine, starch and also cellulose. In addition, a wide range of organic compounds is used as sole sources of carbon for energy and growth (Williams et al., 1983a; Kämpfer et al., 1991b; Korn-Wendisch and Kutzner, 1992a). The optimum temperature for most species is 25–35°C; however, several thermophilic and psychrophilic species are known. The optimum pH range for growth is 6.5–8.0.

The Embden-Meyerhof-Parnas (glycolysis) pathway of glucose catabolism has been found in many streptomycetes (Cochrane, 1961), but also the hexose monophosphate shunt (Salas et al., 1984) was detected in *S. antibioticus*. Several streptomycetes are able to switch from glycolysis to the hexose monophosphate shunt during secondary metabolism (Kieser et al., 2000). At present, no streptomycete is known to use the Entner-Doudoroff pathway. Sugar transport is mediated in connection with phosphorylation by specific kinases (Sabater et al., 1972; Ikeda et al., 1984). The phosphoenolpyruvate:fructose phosphotransferase system (PTS) for the transport and phosphorylation of fructose has recently been detected in *S. coelicolor*, *S. lividans* and *S. griseofuscus* (Titgemeier et al., 1995). More details about specific metabolic pathways, including nitrogen metabolism and the regula-

tion processes involved, are given in chapter 1 of Kieser et al. (2000) and the references therein.

On the basis of 16S rRNA/DNA sequence comparisons, members of the genus *Streptomyces* form a separate line of descent, and Stackebrandt et al. (1997) proposed the emendation of the family Streptomycetaceae in the suborder Streptomycinae and the order Actinomycetales. The intrageneric phylogenetic relationships of many of the 346 recognized species in *Bergey's Manual of Systematic Bacteriology* (Williams et al., 1989) inferred from the 350 complete 16S rRNA sequences, however, are clearly restricted by the limited resolving power of the method to discriminate between related species and are often in contrast with a morphologically and physiologically based classification. Though about 350 almost complete 16S rRNA sequences are available to date, the high degree of conservation within 16S rRNA genes causes problems for resolving phylogenetic relationships at the intergeneric level.

Notably, the different methods used for grouping of the *Streptomyces* species often lead to contradictory results. In Table 4, all 376 *Streptomyces* species and subspecies with valid names (as of December 9, 2003; taken from the List of Bacterial Names with Standing in Nomenclature); and some additional species with names not validly published (but included in taxonomic studies) are given with their grouping according to different studies.

The chemotaxonomic features for the identification of strains at the genus level (for details see below) are of high value and can be summarized as follows: The cell wall peptidoglycan contains major amounts of LL-diaminopimelic acid (LL-A₂pm). Genus members lack mycolic acids, contain major amounts of saturated, *iso*- and *anteiso*-fatty acids, possess either hexa- or octahydrogenated menaquinones with nine isoprene units as the predominant isoprenolog, and have complex polar lipid patterns that typically contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides (Table 2; Figs. 5 and 6). In addition to these traits, the acyl type of the muramyl residues in the cell-wall peptidoglycans is acetyl (Uchida and Seino, 1997). Strains are widely distributed and abundant in soil, including composts (see detailed description below). A few species are pathogenic for animals and man, and others are phytopathogens. The type species is *Streptomyces albus* (Rossi-Doria 1891) Waksman and Henrici (1943).

CELL WALL COMPOSITION

Peptidoglycan The cell walls of streptomycetes show the typical ultrastructure and chemical

Fig. 3. A–J: Color of the aerial mycelium of *Streptomyces* strains grown on different agar media after 3 weeks of incubation at 28°C. Left: starch-casein-nitrate agar; middle: GYM agar; right: oatmeal agar (for compositions, see Tables 10 and 12). Species names and strain numbers are given in Table 7.

composition of Gram-positive bacteria (Schleifer and Kandler, 1972). They appear under the electron microscope as homogeneous less electron dense layers of about 16–35 nm. The cell walls have a multilayered structure of peptidoglycan strands. The peptidoglycan is a heteropolymer consisting of heteropolysaccharide chains cross-linked through short peptide units. The so-called “sugar back bone” of the peptidoglycan is constructed of alternating β -1,4-linked units of *N*-acetylglucosamine and *N*-acetylmuramic acid. The carboxyl group of muramic acid is substituted by an oligopeptide of alternating D- and L-amino acids (Schleifer and Kandler, 1972). *Streptomyces* is characterized by the tetrapeptide L-Ala–D-Glu–LL-A₂pm–D-Ala. This tetrapeptide is crosslinked by a pentaglycine bridge which extends from the C-terminal D-alanine of the peptide unit to the amino group located on the D carbon of LL-A₂pm, resulting in the macromolecule structure forming the cell envelope. This LL-A₂pm–Gly₅, or A₃ γ peptidoglycan type (Schleifer and Kandler, 1972), is diagnostic for streptomycetes and some other combined-wall chemotype I actinomycetes (Lechevalier and Lechevalier, 1970).

The aerobic actinomycetes were grouped (using specific amino acids in purified cell walls) into four so-called “wall chemotypes” by Lechevalier and coworkers. Cell walls with *meso*-DAP and LL-DAP were detected early. In another study, Takahashi et al. (1984b) reported that strains belonging to this group change cell wall composition during sporulation. They found in submerged mycelium LL-DAP and glycine (wall chemotype I) whereas in spores, only *meso*-DAP could be detected (wall chemotype III according to Lechevalier and Lechevalier, 1970). In 11 streptomycetes, the cell wall compositions of aerial, substrate and submerged mycelium differed in the quantitative distribution of cell wall amino acids and cell wall sugars. *N*-Acetylmuramic acid is found in the glycolyl type of cell wall of *Streptomyces*, as in all other actinomycetes (Uchida and Aida, 1977). Muramic acid phosphate residues are the attachment points to teichoic acids, which are of diagnostic value for Gram-positive bacteria. The cell wall teichoic acids (polymeric substances containing repeating phosphodiester groups) consist of polyols (i.e., the sugar alcohols glycerol and ribitol) or *N*-acetyl amino sugars or both. The teichoic acids of streptomycetes are of the same structure as those of other Gram-positive bacteria, containing either ribitol phosphate or glycerol phosphate polymers; significantly, the teichoic acid of actinomycetes does not contain ester-bound D-alanine but does have ester-linked acetic acid and sometimes succinic acid residues (Naumova et al., 1980).

Fig. 5. Two-dimensional thin layer chromatograms of polar lipids of A) *Streptomyces albus* (DSM 40313) and B) *Streptomyces rimosus* (DSM 40260). Abbreviations: DPG, diphosphatidylglycerol; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides; PE, phosphatidylethanolamine; OH-PE, hydroxy-phosphatidylethanolamine; and P, phospholipids of unknown structure. (Courtesy of R. M. Kroppenstedt.)

For streptomycetes, the synthesis of either ribitol phosphate (*S. streptomycini* and *S. violaceus*) or glycerol phosphate polymers (*S. thermovulgaris*, *S. levoris*, *S. rimosus* and *S. antibioticus*) has been reported (Naumova et al., 1980). In ribitol teichoic acids, positions 1 and 5 of ribitols are connected to the phosphates; in glycerol teichoic acids, position 1 is commonly connected to 3; and in other types, position 1 connected to 2 (as in *S. antibioticus*) is not common. The polyol phosphates can be substituted with various combinations of sugars or amino sugars or both, which are linked to glycerols or ribitols via glycosidic bonds. At present, few strains (species) have been investigated in detail and so the role of teichoic acid in the taxonomy of *Streptomyces* is not clear (Naumova et al., 1980).

Cell Wall Polysaccharides These compounds seem to be of no diagnostic value in those strains where LL-DAP is found in whole cell hydrolysates (Lechevalier et al., 1971). Some of the diagnostic sugars found in other actinomycetes, like xylose, galactose and arabinose, were reported occasionally in streptomycetes. Hundreds of streptomycetes were analyzed for the presence of diagnostic sugars (Kroppenstedt, 1977), and mainly ribose, mannose and glucose were usually found in small amounts.

Phospho- and Glycolipids The lipids of streptomycetes comprise mainly diphosphatidylglycerol (DPG), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylinositol-mannosides (PIMs). Lipid composition has been extensively investigated and summarized by Lechevalier et al. (1977b). Glycolipids do not occur consistently in streptomycetes, and their

qualitative and quantitative lipid composition depends largely on culture conditions. Under phosphate limiting conditions, the amount of glycolipids increase, significantly.

The taxonomic significance of polar lipids in actinomycetes was demonstrated by Lechevalier et al. (1977b). From the phospholipid results of 97 actinomycete strains representing 20 genera, Lechevalier et al. (1977b) proposed a classification of five phospholipid types. These five groups are based on the presence or absence of certain nitrogenous phospholipids. The marker lipids of type II (PII) are phosphatidylethanolamine (PE), methyl-PE, hydroxy-PE, and lyso-PE. In addition to various other families, members of the family Streptomycetaceae contain the lipids of phospholipid type II. Additional lipids (e.g., phosphomonoester [PME] and OH-PE) and the presence or absence of PI and PG allow further differentiation (Fig. 5).

MENAQUINONES Streptomycetes contain only menaquinones (Collins and Jones, 1981), and like the majority of actinomycetes, they synthesize quinones that have a partly saturated isoprenoid side chain at position 3 of the naphthoquinone ring. Menaquinone composition is very useful for differentiation of actinomycetes because of the different numbers of isoprene units, the different degree of hydrogenation, and the position of hydrogenated isoprene units (Table 2). These three variations are useful for classification and identification. Streptomycetes synthesize menaquinones with a highly hydrogenated isoprenoid chain. Three to four (rarely five) isoprene units are saturated. The actinomycetes which belong to this type synthesize menaquinones with the same chain length but different degree of saturation (Fig. 6).

Fig. 6. Menaquinone profile of *Streptomyces griseus* (DSM 40236). The extent of hydrogenation of the isoprene units is shown by the subscript of the abbreviation. For instance, MK-9 (H_8) is a menaquinone with four hydrogenated isoprene units. (Courtesy of R. M. Kroppenstedt.)

Phenotypic Methods for Classification within the Genus *Streptomyces*

Phenotypic methods comprise all those that are not directed towards DNA or RNA. They include also chemotaxonomic techniques. Between 1916 and 1943, most of the studies on streptomycetes were published by soil microbiologists, who were mainly interested in ecological questions. Only few species were described at that time, mainly on the basis of morphological criteria, pigmentation and ecological requirements (Waksman and Curtis, 1916; Waksman, 1919; Jensen, 1930).

The discovery of actinomycin from *S. antibioticus* (Waksman and Woodruff, 1940) was the starting point of the investigations of antibiotics and other bioactive substances produced by streptomycetes in the 1940s and this led to extensive screening approaches for novel bioactive compounds in the following two decades.

The description of each producer of a novel natural product as a new species (often patented) led to an explosion of species descriptions and resulted in an overclassification of the genus. In the 1970s, the number of species increased to over 3000 (Trejo, 1970).

Reduction in the number of species names was first attempted in 1964 by the International *Streptomyces* Project (ISP), which introduced standard criteria for determining species (described in Shirling and Gottlieb, 1968a, Shirling and Gottlieb, 1968b, Shirling and Gottlieb, 1969, and Shirling and Gottlieb, 1972) to reduce the number of poorly described synonymous species. The major drawback of these descriptions was that they were based mainly on morphology (i.e., spore chain morphology, spore

surface ornamentation, color of spores, substrate mycelium, soluble pigments, and production of melanin pigment), in addition to a few physiological properties, which were mainly restricted to utilization tests of different carbon sources.

In these classical papers, more than 450 *Streptomyces* species were redescribed, and type strains were deposited in internationally recognized culture collections. Although intended, the efforts of the ISP did not result in an applicable identification scheme.

A first step in this direction was the development of numerical taxonomic methods in the 1960s including the methods of numerical identification. The first numerical taxonomic studies of streptomycetes by Silvestri et al. (1962) found considerable diversity within the genus but also groups that corresponded to the initial morphological descriptions. These studies did not result in nomenclatural changes, and despite the development of other small databases for identification of streptomycetes (Kurylowicz et al., 1975; Gyllenberg, 1976), these studies had no impact on streptomycetes systematics (Table 3). Data from a large-scale numerical taxonomic study by Williams et al. (1983a) of 475 strains (including 394 *Streptomyces* type cultures from the ISP) for 139 unit characters were analyzed with simple matching, the Jaccard coefficient, and the average linkage algorithm. Consequently, the genus *Streptomyces* was subdivided into species groups. *Streptomyces* type strains (394) were clustered according to similarities obtained from the phenetic tests. At the $77 \pm 5\%$ simple matching coefficient (S_{SM}) level, 19 major, 40 minor and 18 single strain clusters were recovered. Many of the minor clusters consisted of less than five strains. Major clusters varied in size from 6 to 71 strains. Each cluster was addressed as a single "species" despite the high diversity observed

within some clusters, and these therefore were addressed as “species groups.” The largest species group is *Streptomyces albidoflavus* (cluster 1), containing 71 strains, including 44 type strains, 15 invalidly published species, and 12 unnamed strains. This cluster is further subdivided into three clusters: cluster 1a, *Streptomyces albidoflavus* subsp. *albidoflavus* (20 strains), cluster 1b, *Streptomyces albidoflavus* subsp. *anulatus* (38 strains), and cluster 1c, *Streptomyces albidoflavus* subsp. *halstedii* (13 strains; Williams et al., 1989).

The high phenotypic diversity of this cluster is obvious from the different test pattern. All strains produced yellow gray colonies, produced smooth spores in straight chains and no melanin, and exhibited resistance to a number of antibiotics including penicillin, lincomycin and cephaloridine. Many of the strains showed also antimicrobial activity; 39% produced compounds with antifungal activity, 32% produced compounds active against Gram-positive microorganisms and 10% against Gram-negative microorganisms (Williams et al., 1983b), showing the large diversity within one cluster and exemplifying clearly the problems with streptomycete systematics (Anderson and Wellington, 2001).

Nevertheless, the comprehensive survey of Williams et al. (1983a) resulted subsequently in a reduction of the number of described *Streptomyces* species; however, the problem of over-speciation remained. Numerous species and subspecies were described and many natural isolates did not match the reference strains used to construct the identification matrices (Goodfellow and Dickenson, 1985). Although probability matrices for identification purposes were published (Williams et al., 1983b; Langham et al., 1989), these matrices were not widely adopted by the scientific community.

This study was the basis of the taxonomic scheme for streptomycetes presented in the 1989 edition of *Bergey's Manual of Systematic Bacteriology*, in which 142 species are listed (Williams et al., 1989), in contrast to 463 species described in the 1974 edition of *Bergey's Manual of Determinative Bacteriology* (Pridham and Tresner, 1974). A further numerical taxonomic analysis by Kämpfer et al. (1991b) included more strains and more than one strain of each species when available. A total of 821 strains were tested for 329 physiological properties, and the resulting cluster analysis was compared with the data published by Williams et al. (1983a) in addition to published genetic and chemotaxonomic data.

Many of the clusters defined by Williams et al. (1983a) were again recognized; for example the *S. albidoflavus*, *S. anulatus*, *S. griseus*, *S. halstedii* group appeared as cluster 1 in both studies, in which 28 of the *S. griseus* strains were grouped.

Interestingly, most of the strains sharing the same specific epithet were grouped together, indicating previous identification was reliable, but some exceptions were also observed. For example *S. hygroscopicus* strains were recovered in cluster 1 but also in several other clusters and subclusters.

On the basis of this study, a probability matrix was constructed (Kämpfer and Kroppenstedt, 1991a), but this matrix was likewise not widely used by other research groups.

Parallel with the numerical taxonomic studies, additional chemotaxonomic and also molecular methods were developed that are now often used together with (often) few physiological tests to study streptomycetes; however, a clear species concept is still pending. In Table 4, the cluster allocation of the species is given in comparison.

Other phenotypic methods include cell wall analysis (Lechevalier and Lechevalier, 1970), fatty acid profiling (Hofheinz and Grisebach, 1965; Lechevalier, 1977a; Saddler et al., 1986; Saddler et al., 1987; Kroppenstedt, 1992), rapid biochemical assay for utilization of 4-methylumbelliferone-linked substrates (Goodfellow et al., 1987c), serological assay (Ridell et al., 1986), phage typing (Wellington and Williams, 1981a; Korn-Wendisch and Schneider, 1992b), and protein profiling (Manchester et al., 1990; Goodfellow and O'Donnell, 1993; Lanoot et al., 2002), including comparison of ribosomal protein patterns (Ochi, 1989; Ochi, 1992; Ochi, 1995).

Fatty acids

The initial studies on actinomycete fatty acids were carried out by Hofheinz and Grisebach (1965) on *Saccharopolyspora erythraeus* (formerly “*Streptomyces erythraeus*”) and *Streptomyces halstedii* to elucidate the biosynthetic pathway of branched fatty acids. It was shown that streptomycetes synthesize terminally branched fatty acids. *Anteiso*-branched fatty acids are synthesized from 2-methylbutyrate, leading to *anteiso* fatty acids with an odd number of carbon atoms. In contrast, isovalerate and isobutyrate as starting compounds lead to the formation of *iso*-branched fatty acids with even and odd numbers of C-atoms, respectively. For this reason *iso*- and *anteiso*-branched fatty acids appear in pairs with odd numbers of C-atoms only.

In their early studies, Hofheinz and Grisebach (1965) separated the fatty acids as their methyl esters by gas chromatography on different stationary phases. Identification of the individual fatty acids was obtained by comparing the equivalent chain lengths of unknown fatty acids with those of standard mixtures. The results were confirmed by preparative gas-chromatography and by physical methods such as mass spectrometry

and nuclear magnetic resonance (NMR) spectrometry. In both species, *iso*- and *anteiso*-branched fatty acids with chain lengths of 15 and 17 carbon atoms were detected. High amounts of 14-methyl pentadecanoic acid (*iso*-C16:0) were found in addition, while minor amounts of unbranched fatty acids, tuberculostearic acid and their homologues, could be detected in "*S. erythraeus*" (now *Saccharopolyspora erythraea*) but not in *Streptomyces halstedii*. These results are congruent with those of several other studies (Lechevalier et al., 1977a; Saddler et al., 1985; Saddler et al., 1987) in which 10-methyl branched fatty acids could not be detected among streptomycetes. Usually only small amounts of hydroxy fatty acids are synthesized by a limited number of streptomycetes under optimal oxygen supply. The hydroxy fatty acids are easily destroyed in a non-deactivated injection port of capillary gas chromatography system. Therefore hydroxy fatty acids in streptomycetes often go unnoticed. If streptomycetes are grown under reproducible culture conditions, the hydroxy fatty acids they produce are highly diagnostic for some streptomycetes species. Hydroxy fatty acids were detected in all strains of *S. coelicolor* (30), *S. rimosus* (14), and *S. violaceusniger* (18) and in 20 of 27 *S. hygroscopicus* strains but not in *S. violaceoruber* (16), *S. lavendulae* (18), *S. griseus* (22), *S. fradiae* (25), *S. viridochromogenes* (25), *S. glaucescens* (8) and *S. albus* (33; Kroppenstedt, 1992; R. M. Kroppenstedt, unpublished observation). Standardized growth and cultivation conditions are a general prerequisite for the use of fatty acid patterns below the genus level (Saddler et al., 1986). Saddler et al. (1987) used fatty acid profiles to investigate the taxonomy of *Streptomyces cyaneus* strains and soil isolates showing also blue spores. The *S. cyaneus* cluster harbors 13 of 19 blue-spored strains of streptomycetes (Hütter, 1962; Pridham and Tresner, 1974; Korn et al., 1978). In the study of Saddler et al. (1987), 8 of their 10 blue-spored isolates clustered, while 17 of the 34 *S. cyaneus* strains were assigned to a separate cluster. The conclusions of the fatty acid study (Saddler et al., 1987) and Williams et al. (1983a) agree that conventional features like spore chain morphology, color and ornamentation of spores may be helpful for presumptive identification but are not definitive for classification of streptomycetes. The same combination of features may be found in different clusters, yet one cluster may have members with different features. The study of Saddler et al. (1987), however, demonstrated also the heterogeneity of the *Streptomyces cyaneus* taxon as defined by Williams et al. (1983a). Fatty acid patterns in general cannot delimit *Streptomyces* species (Phillips, 1992; R. M. Kroppenstedt, unpublished observation), but using standardized conditions, they are still of high

value for the rapid characterization (independent of the taxonomic status) of large numbers of wild-type streptomycetes isolated from the environment (Saddler et al., 1987). By using the automated commercially available MIDI system consisting of a Hewlett-Packard model 5890 capillary gas chromatograph and a computer with specific software (Microbial ID, Inc., Newark, DE), the fatty acids are automatically identified and quantified by the computer using fatty acid standard mixtures for comparison. In their chapter on The Family Nocardiopsaceae in this Volume, Kroppenstedt and Evtushenko give a table of types and the fatty acids diagnostic for different genera of Actinomycetales, including *Streptomyces*. The comparison of different methods revealed that the use of numerical methods to determine taxonomy lumped too many strains together into some clusters (Williams et al., 1983a; Kämpfer et al., 1991b).

Curie-point Pyrolysis Mass Spectrometry (PyMS)

This method has also been applied to the classification and identification of actinomycetes (Sanglier et al., 1992). Similar to fatty acid profiling, highly standardized conditions are necessary. Whole cells are subject to high temperatures and subsequent nonoxidative thermal degradation. The resulting pyrolysate is then analyzed using mass spectrometry, resulting in a fingerprint for each organism.

Sanglier et al. (1992) applied this method to strains belonging to the largest *Streptomyces* species group, *Streptomyces albidoflavus*. Interestingly, *Streptomyces albidoflavus* and *Streptomyces anulatus* strains could be separated into distinct groups. Three of the six *Streptomyces halstedii* strains investigated also clustered into a distinct group, whereas the remaining strains clustered into two other groups. The study of Kämpfer et al. (1991b) also found that *Streptomyces albidoflavus* strains and *Streptomyces anulatus* strains grouped separately. Interestingly, it was confirmed that *Streptomyces anulatus* ISP 5361^T, the strain used to name the *Streptomyces anulatus* cluster, formed also a single-member cluster (Table 4).

Serology

Few results using serological methods have been published. Antisera against the mycelia from streptomycetes, streptovorticillia and *Nocardioopsis* species (Ridell et al., 1986) were used to confirm the high similarity between *Streptomyces lavendulae* and the streptovorticillia (Witt and Stackebrandt, 1990; Kämpfer et al., 1991b). The antisera of Kirby and Rybick (1986) raised against *Streptomyces griseus* (*Streptomyces anu-*

Modified from Anderson and Wellington (2001).

latus, cluster 1B of Williams et al., 1983a) and "*Streptomyces cattleya*" (cluster 47) were shown to be genus-specific and to a certain degree also group-specific. The monoclonal antibody produced by Wipat et al. (1994) to "*Streptomyces lividans*" 1326 was shown to be specific for "*Streptomyces lividans*" strain 1326. Interestingly, antigenic reaction was observed also for strains grouped into cluster 21 of Williams et al. (1983a).

Phage Typing

Phage typing can be used for host identification at the genus and the species level (Welsch et al., 1957; Kutzner, 1961a; Kutzner, 1961b; Korn et al., 1978; Wellington and Williams, 1981a). Many actinophages (most of them virulent) for phage typing have been described. Streptomycete phages can be either polyvalent (e.g., C31; Chater et al., 1986b) or species-specific (Anderson and Wellington, 2001; Table 5). The specificity of actinophages at the genus level (e.g., Wellington and Williams, 1981a; Korn-Wendisch, 1982; Prauser, 1984) was an additional feature that justified the transfer of *Actinopycnidium*, *Actinosporangium*, *Chainia*, *Elytrosporangium*, *Microellobosporia*, *Kitasatoa* and *Streptoverticillium* to the genus *Streptomyces* (Goodfellow et al., 1986b; Goodfellow et al., 1986c; Goodfellow et al., 1986d; Goodfellow et al., 1986e; Witt and Stackbrandt, 1990). Other transfers justified by phage specificity include *Actinoplanes armeniacus* to the genus *Streptomyces* (Kroppenstedt et al., 1981; Wellington et al., 1981b) and "*S. erythraeus*" to the genus *Saccharopolyspora* (Labeda, 1987). Species or group identification of *Streptomyces* using phage typing has been less successful, but there are a few exceptions (Table 5).

Phages are also useful in industrial microbiology studies (Carvajal, 1953; Ogata, 1980) and in genetic studies (for review, see Chater [1986a] and chapter 12 of Kieser et al. [2000]). One of the best-investigated actinophages is C31, a temperate phage with a broad host range within the genus *Streptomyces* (Lomovskaya et al., 1980). This phage has become the subject of extensive studies and has been employed for many purposes (e.g., transfection, transduction, detection of transposon-like elements of host DNA, and cloning). Details are given in chapter 12 of Kieser et al. (2000).

Protein Profiling

Polyacrylamide gel electrophoresis (PAGE) of total protein extracts generate more or less complex banding patterns. These patterns can be used to differentiate species and subspecies within various bacterial genera. Protein patterns can be determined using one-dimensional (1-D) or two-dimensional (2-D) protein electrophoresis. The protein profiles of streptomycetes were first analyzed by Manchester et al. (1990), who investigated 37 *Streptomyces* strains (among them 5 streptoverticillia). Some taxonomic correlations were found between these profiles and the phenotypic groupings observed by Williams et al. (1983a) and Kämpfer et al. (1991b) in addition to some DNA hybridization groupings (Table 4). But Lanoot et al. (2002) confirmed only a few of these correlations. For *Streptomyces* isolates that are the causal agent of common potato scab, Paradis et al. (1994) used both PAGE and DNA-DNA hybridizations to elucidate the taxonomy of their strain. Isolates obtained from potato tubers were divided into two groups with a correlation coefficient of 0.75

using sodium dodecylsulfate (SDS)-PAGE analysis. The same two groups were resolved at approximately 44% similarity using DNA-DNA hybridization analysis. The fatty acid analysis results of the same study did not correlate with the SDS-PAGE and the DNA-DNA hybridization groupings, which can be explained by the influence of growth conditions on the profiles obtained (Saddler et al., 1986; Saddler et al., 1987). Protein profiling was not able to differentiate pathogenic from nonpathogenic strains.

Other more specific patterns are obtained with multilocus enzyme electrophoresis (MLEE) and depend on the relative mobilities of cellular enzymes in a gel matrix. Oh et al. (1996) studied 24 *Streptomyces* strains and demonstrated how MLEE could be used for both inter- and intraspecific characterization of streptomycetes, provided the appropriate enzymes were used. However, because only a restricted set of strains was studied, no general recommendations can be made for the usefulness of this method. In a more comprehensive study, 93 *Streptomyces* reference strains were investigated using SDS-PAGE of whole-cell proteins (Lanoot et al., 2002). Subsequent computer-assisted numerical analysis revealed 24 clusters encompassing strains with very similar protein profiles. Five of them included several type strains with visually identical patterns. DNA-DNA hybridizations revealed similarities higher than 70% among these type strains. On the basis of these results, consideration of *Streptomyces albosporus* subsp. *albosporus* LMG 19403^T as a subjective synonym of *Streptomyces aurantiacus* LMG 19358^T, *Streptomyces aminophilus* LMG 19319^T as a subjective synonym of *Streptomyces cacaoi* subsp. *cacaoi* LMG 19320^T, *Streptomyces niveus* LMG 19395^T and *Streptomyces spheroides* LMG 19392^T as subjective synonyms of *Streptomyces caeruleus* LMG 19399^T, and *Streptomyces violatus* LMG 19397^T as a subjective synonym of *Streptomyces violaceus* LMG 19360^T was proposed (Table 4).

Two-dimensional PAGE of the total cellular proteins allows a finer resolution of the individual gene products. This technique results in very complex patterns and seems to be too sensitive to investigate proteins with high rates of evolution (Hori and Osawa, 1987). Mikulik et al. (1982) and later Ochi (1989) were the first to apply 2-D PAGE to determine the variability of ribosomal proteins for use in streptomycete taxonomy. These studies were later extended by focusing on AT-L30 proteins, which give genus-specific profiles (Ochi, 1992). In an even more specific analysis, Ochi (1995) correlated the N termini sequences of the ribosomal AT-L30 protein of 81 streptomycete strains from different taxonomic groups to phylogenetic groupings

within the genus and pointed out that on this basis the genus *Streptomyces* seems to be well described. However, Ochi's groupings did not correlate with those of Williams et al. (1983a) and Kämpfer et al. (1991b). For details of these groupings, see Table 4.

More detailed taxonomic studies of *Streptomyces* have been performed by isolating and sequencing specific proteins. For example, Taguchi et al. (1996) used the *Streptomyces* subtilisin inhibitor protein (SSI), which plays unidentified role(s) in physiological or morphological regulation, to investigate the taxonomic status of the *Streptomyces coelicolor* strains. The amino acid sequence, of SSI from "*Streptomyces lividans*" 66, *Streptomyces coelicolor* Müller ISP 5233^T and "*Streptomyces coelicolor*" A3(2) were compared. The alignments supported ribosomal sequence comparisons, indicating that "*Streptomyces coelicolor*" A3(2) is more closely related to "*Streptomyces lividans*" 66 (cluster 21 of Williams et al., 1983a) than to the type strain, *Streptomyces coelicolor* Müller ISP 5233^T (cluster 1).

Genotypic Methods for Classification within the Genus *Streptomyces*

Genotypic methods comprise all those that are directed towards DNA or RNA molecules (Schleifer and Stackebrandt, 1983; Vandamme et al., 1996). The development of molecular methods to analyze bacterial genomes has provided a new basis for studying bacterial taxonomy and in some cases phylogenetic relationships of the prokaryotes at the genus, species and subspecies level. These methods are widely used in modern taxonomic studies. The general taxonomic values of different molecular techniques are given by Vandamme et al. (1996) and in Prokaryote Characterization and Identification in Volume 1. Their usefulness in taxonomic studies to delimit species within the genus *Streptomyces* is discussed briefly in the following chapters and has also been reviewed by Anderson and Wellington (2001).

Problems in assigning new strains to existing species on the basis of this molecule alone persist and doing this will not be possible in the future. As already pointed out by Stackebrandt and Schumann in Introduction to the Classification of the Actinomycetes in this Volume, comparative analysis of sequences of homologous and genetically stable semantides has demonstrated that several classification systems based on morphology and physiology do not reflect the natural relationships among actinomycetes and related organisms. In this respect, rRNA sequence com-

parison is a powerful tool in modern taxonomy and has revolutionized our insight in phylogenetic lineages of major taxonomic groups. However, the resolving power of 16S rRNA sequences is not sufficient to delimit species. Nevertheless, rRNA sequence comparisons are important in the taxonomy of *Streptomyces* and the results have also been used to answer questions about horizontal transfer of genes within the genus (Huddleston et al., 1997). Genes for 16S RNAs are highly conserved within bacteria. Within the genus *Streptomyces*, three regions within the gene have enough sequence variation to be useful as genus-specific (*a* and *b* regions) and species-specific (*c* regions) probes (see Stackebrandt et al., 1991a; Stackebrandt et al., 1991b; Stackebrandt et al., 1992; Anderson and Wellington, 2001). Not only 16S rRNA genes, but also 23S rRNA and 5S rRNA genes (Mehling et al., 1995), 16S-23S rRNA internally transcribed spacer (ITS) sequences (Song et al., 2003), and ribosomal protein sequences have also been used to investigate species relationships within the genus *Streptomyces* (Liao and Dennis, 1994; Ochi, 1995). Wenner et al. (2002) studied the nucleotide composition of the ITS sequences of the six rDNA operons of two *Streptomyces ambofaciens* strains. Their findings suggested that recombination frequently occurs between the rDNA loci, leading to the exchange of nucleotide blocks, and confirmed that a high degree of ITS variability is a common characteristic among *Streptomyces* spp. Note that rRNA sequences cannot be used alone because of the intraspecific variation and intragenomic heterogeneity.

DNA-DNA Hybridizations

The percent DNA-DNA hybridization and the decrease in thermal stability of the hybrid are at present the “gold standard” methods of species delineation in bacteriology (Wayne et al., 1987). An ad hoc committee for the re-evaluation of the species definition in bacteriology (Stackebrandt et al., 2003) has encouraged investigators to verify the species concept with other methods; however, DNA-DNA similarity and change in melting temperature (ΔT_m ; Wayne et al., 1987) remain the acknowledged standard for definition of species.

DNA-DNA hybridizations of total chromosomal DNA have also been used within the genus *Streptomyces*. In an initial study, Mordarski et al. (1986) compared the numerical and phenetic groupings of strains of the *Streptomyces albidoflavus* cluster 1 of Williams et al. (1983a) with the results of DNA-DNA hybridizations (reassociation of labeled DNA on nitrocellulose filters). In congruence with numerical studies, DNA-DNA hybridization studies showed this

cluster could be subdivided into three subclusters and confirmed the homogeneity of the *Streptomyces albidoflavus* subcluster *albidoflavus*. Two further subclusters obtained by DNA-DNA hybridizations were not congruent with the groupings of *S. anulatus* or *halstedii* by Williams et al. (1983a); however, some correlations were found with the groupings of Kämpfer et al. (1991b). Unification using DNA-DNA similarity (Witt and Stackebrandt, 1990) of *Streptovorticillum* strains with the genus *Streptomyces* (reassociation of labeled DNA on filters) was confirmed by phenotypic data in the numerical study of Kämpfer et al. (1991b).

The most extensive application of DNA-DNA hybridizations (thermal renaturation method) to the study of the major streptomycete phenetic groups of Williams et al. (1983a) was by Labeda and coworkers. In studies using *Streptomyces cyaneus* (Labeda and Lyons, 1991a), *Streptomyces violaceusniger* (Labeda and Lyons, 1991b), *Streptomyces lavendulae* (Labeda, 1993), the verticillium-forming streptomycetes (formerly *Streptovorticillum* species; Labeda, 1996; Hatano et al., 2003), and *S. fulvissimus* and *S. griseoviridis* phenotypic clusters (Labeda, 1998), the degree of DNA similarities was often not congruent with the phenetic groupings of Williams et al. (1983a). But again, more correlations were found with the groupings of Kämpfer et al. (Kämpfer et al., 1991b; Table 4). The usefulness of the DNA-DNA hybridization technique to delineate species within the genus *Streptomyces* has been questioned. In support of the usefulness of this technique is the considerable genetic instability of certain regions within the *Streptomyces* chromosome (Redenbach et al., 1993). The two complete *Streptomyces* genome sequences available at this time (Omura et al., 2001; Ikeda et al., 2003) indicate that the central core region contains mostly the essential housekeeping genes, while the chromosome arms comprise laterally acquired contingency genes. Another issue is the presence of large plasmids in strains of *Streptomyces*, which can considerably influence the results of DNA-DNA hybridizations. General properties of *Streptomyces* plasmids and their use for gene cloning are given in chapter 11 of Kieser et al. (2000).

Fingerprinting Techniques

RANDOMLY AMPLIFIED POLYMORPHIC DNA (RAPD) POLYMERASE CHAIN REACTION (PCR) RAPD-PCR is used as a rapid screening method to detect similarity among streptomycete strains. Single primers with arbitrary nucleotide sequences to amplify DNA are used in addition to a low annealing temperature so that polymorphisms can be detected. Stringent standardiza-

tion of the reaction parameters is required. These include primer sequence, annealing temperatures, buffer components, concentration and quality of template DNA. The resulting characteristic fingerprint of PCR products enables detection of chromosomal differences between individual isolates without having any prior knowledge of the chromosomal sequence (Williams et al., 1990). Applying this technique, Mehling et al. (1995) could not detect any characteristic banding patterns for closely related species unless a highly specific actinomycete primer was used. As a major disadvantage, the resulting fingerprints contained only few bands (one to four), reducing the effectiveness of this method. Huddleston et al. (1995) reported similar results. They evaluated the use of RAPD-PCR for the resolution of interspecific relationships among members of the *Streptomyces albidoflavus* cluster of Williams et al. (1983a). Anzai et al. (1994) demonstrated the variation in fingerprints obtained when a single base was substituted on the arbitrary primer; 11 primers were investigated and the number of bands ranged from zero to 20. The most significant differences were observed when the sequence at the 3' end was altered. Anzai et al. (1994) also investigated the relationship of *Streptomyces virginiae* strains to *Streptomyces lavendulae* strains by RAPD-PCR. Williams et al. (1983a) found that *Streptomyces virginiae* was a synonym of *Streptomyces lavendulae*. These strains were also grouped into the same cluster in the study of Kämpfer et al. (1991b). In addition to RAPD-PCR, DNA-DNA hybridization, low-frequency restriction fragment analysis (LFRFA), and cultural and physiological tests were performed. Consistent results were obtained using all these methods after RAPD PCR optimization. It was however not possible to clarify the interspecific relationship of *Streptomyces lavendulae* and *Streptomyces virginiae*.

RESTRICTION DIGESTS OF TOTAL CHROMOSOMAL DNA Similar to the RAPD PCR techniques, low-frequency restriction fragment analysis (LFRFA) uses the entire bacterial chromosome, which is digested with restriction endonucleases that cut infrequently. Because streptomycetes belong to bacteria with a high DNA G + C content, rare AT cutters are used. The fragments obtained were separated by pulsed-field gel electrophoresis (PFGE). In a first study, Beyazova and Lechevalier (1993) included 59 strains from eight species groups and found the method useful for the clustering of related strains. However, some discrepancies were found, for example for strains grouped into the *Streptomyces cyaneus* cluster of Williams et al. (1983a). Again this method seems to be useful for the detection of

very closely related strains, but similar to RAPD-PCR, it cannot resolve interspecific relationships. In addition, Rauland et al. (1995) found that large chromosomal amplifications or deletions may also lead to misinterpretations of resulting banding patterns.

NUCLEIC ACID SEQUENCE COMPARISONS OF 16S rRNA AND OTHER GENES The application of 16S rRNA gene sequence analysis to the study of the taxonomy of streptomycetes is reviewed by Stackebrandt et al. (1992), who highlighted the importance of the region selected for comparison. Sequence analysis of rRNA genes has already been applied at the genus, species and strain level. The relationships obtained differed considerably depending on the variable region (*a*, *b* or *c*). Kataoka et al. (1997) subsequently investigated the *c* region from 89 streptomycete type strains representing several clusters of Williams et al. (1983a). Though these variable regions were useful for resolving inter- and intraspecies relationships within the streptomycetes, they were too variable for determining generic relationships. Among the 89 strains studied, 57 variants were detected and 42 strains were found to have unique sequences. After this publication, the *c* regions from 485 streptomycete strains were sequenced and deposited in GenBank by this group. At present, this is the largest publically available set of streptomycete 16S rDNA sequence data.

Anderson and Wellington (2001) published a phylogenetic tree based on comparison of the *c* regions from representatives of the major cluster groups defined by Williams et al. (1983a). The taxonomic status of the phenotypic groups was confirmed, although they did not cluster together. Only *Streptomyces olivaceoviridis* and *Streptomyces griseoruber* strains (which are found in clusters 20 and 21 of Williams et al. [1983a], but in a single cluster 9 of Kämpfer et al. [1991b]) had identical *c* regions. The *Streptomyces albidoflavus* group, which was previously divided into three species groups by Williams et al. (1983a) and contained more than 60 strains (Williams et al., 1989), was now divided into six groups using sequence comparisons of the *c* region (Kataoka et al., 1997). The three phenotypic subgroups of Williams et al. (1983a) were maintained but did not cluster together.

Hain et al. (1997) designed 16S rRNA oligonucleotide probes to determine intraspecific relationships within the *Streptomyces albidoflavus* group. As a result, sequence comparisons were found to be useful for species delimitation but of no value for strain differentiation.

Also the intergenic 16S-23S rRNA spacer regions were investigated in detail and they were obviously more suitable for delineation of the

intraspecific relationships within that cluster. Genus specific probes based on 23S rRNA gene sequences (Mehling et al., 1995) and 5S rRNA gene sequences (Park et al., 1991) have been developed. The reclassification of the genera *Chainia*, *Elytrosporangium*, *Kitasatoa*, *Microellobosporia* and *Streptoverticillium* into the genus *Streptomyces* (Park et al., 1991) was confirmed using 5S rRNA gene sequence evaluation.

At present about 350 complete 16S rRNA sequences are available from public databases. Although 16S rRNA sequence analyses have provided a framework for prokaryotic classification, note that the current classification system based on this molecule has not yet solved the taxonomy within the genera (especially within the genus *Streptomyces*). Several studies have attempted to use sequence data from variable regions of 16S rRNA to establish taxonomic structure within the genus, but the variation is too limited to help resolve problems of species differentiation (Witt and Stackebrandt, 1990; Stackebrandt et al., 1991b; Stackebrandt et al., 1992; Anderson and Wellington, 2001).

The situation is complicated by the fact that *Streptomyces* species may harbor different 16S rRNA gene sets. For example, *S. coelicolor* A3(2), *S. lividans* and several *Streptomyces* species harbor six ribosomal rRNA gene sets. Each set comprises one gene copy for 16S, 26S, and 5S rRNA (Van Wezel et al., 1991) and lacks tRNA genes.

A comprehensive study of the phylogenetic relationships between 64 whorl-forming streptomycetes using partial *gyrB* sequences (the structural gene of the B subunit of the DNA gyrase) has been published by Hatano et al. (2003). The strains in this study consisted of 46 species and eight subspecies and in addition 13 species whose names have not been validly published (including 10 strains examined by the International *Streptomyces* Project [ISP]). Two major groups were found. The typical whorl-forming species (59 strains) were further divided into six major clusters of three or more species, seven minor clusters of two species, and five single-member clusters on the basis of the threshold value of 97% *gyrB* sequence similarity. Major clusters contained *Streptomyces abikoensis*, *Streptomyces cinnamoneus*, *Streptomyces distallicus*, *Streptomyces griseocarneus*, *Streptomyces hiroshimensis* and *Streptomyces netropsis*. Phenotypically, members of each cluster resembled each other closely except for those in the *S. distallicus* cluster (which was divided phenotypically into the *S. distallicus* and *Streptomyces stramineus* subclusters) and the *S. netropsis* cluster (which was divided into the *S. netropsis* and *Streptomyces eurocidicus* subclusters). Strains in each minor cluster closely resembled each other phenotypi-

cally. At the conclusion, 59 strains of typical whorl-forming *Streptomyces* species were placed into the following 18 species, including subjective synonym(s): *S. abikoensis*, *Streptomyces arduus*, *Streptomyces blastomyceticus*, *S. cinnamoneus*, *S. eurocidicus*, *S. griseocarneus*, *S. hiroshimensis*, *Streptomyces lilacinus*, "*Streptomyces luteoreticuli*," *Streptomyces luteosporeus*, *Streptomyces mashuensis*, *Streptomyces mobaraensis*, *Streptomyces morookaense*, *S. netropsis*, *Streptomyces orinoci*, *S. stramineus*, *Streptomyces thioluteus* and *Streptomyces viridiflavus* (Table 4). All strains showing 98.5–100% *gyrB* sequence similarity also had a high DNA-DNA similarity (70–100%), showing better resolution with *gyrB* sequences than with 16S rRNA sequences.

Other genes known to be conserved between species, such as housekeeping genes (e.g., elongation factors and ATPase subunits), may be useful as primary target genes for study (Ludwig and Schleifer, 1994). Huddleston et al. (1997) used tryptophan synthase genes in addition to 16S rRNA gene comparisons to determine the phylogeny of streptomycin-producing streptomycetes and provide evidence for the horizontal transfer of antibiotic resistance genes. Predictably, sequence information on other genes (i.e., other housekeeping genes) will lead to better insight into the intraspecific structure of the genus *Streptomyces* (Stackebrandt et al., 2003).

Rapid Methods for Gene Analysis in Streptomycete Taxonomy

Several alternative methods have been described that do not involve sequencing, using either restriction analysis (Clarke et al., 1993; Fulton et al., 1995) or specialized gel electrophoresis techniques to monitor the mobility of the product (Hain et al., 1997; Heuer et al., 1997). Restriction fragment length polymorphism (RFLP) patterns of purified rRNA were used by Clarke et al. (1993) with strains from the *Streptomyces albidoflavus* cluster (subgroups 1A and 1B of Williams et al., 1983a). The following combination of enzymes was used: *Bgl*II, *Eco*RI, *Pst*I and *Pvu*II. The resulting RFLP profiles varied considerably between species groups but were found to enable differentiation of phenotypically similar strains. Fulton et al. (1995) performed ribosomal restriction analysis using *Mse*I fingerprints of rRNA operons (RiDiTS) to group 98 named streptomycete strains including members of cluster group A (comprising clusters 1–41) and F (comprising clusters 55–67) of Williams et al. (1983a) and other strains. The resulting RiDiTS belonged to 11 pattern types with varying degrees of similarity to the Williams subclusters. At low resolution (70% similarity), cluster groups A and F

could be differentiated, but individual clusters could not.

Further studies are based on genotypic variation monitored using denaturing gradient gel electrophoresis (DGGE; Muyzer et al., 1993) with or without DNA-binding agents (Hain et al., 1997). Anderson and Wellington (2001) recommended DGGE in combination with other techniques. Using the variable 16S rRNA regions, this method enables delimitation of genus groups and species-groups. Huddleston et al. (1995) allocated isolates ASB33, ASB37 and ASSF22 to *Streptomyces albidoflavus*, *Streptomyces griseoruber* and *Streptomyces albidoflavus*, respectively, using a combination of techniques including numerical taxonomy, PFGE and sequence comparisons (Huddleston et al., 1997).

Identification of Streptomycetaceae at the Genus Level

Sequencing of 16S rRNA genes and comparison of these sequences after careful alignment with published sequences is currently the most reliable method for assigning unknown organisms to the different genera. The calculation of phylogenetic trees at the subgeneric level should be done very carefully and may lead to misinterpretations. Notably, phylogenetic analysis on the basis of 16S rRNA comparisons does not allow species delineation.

Colony morphology (color of the aerial mycelium, color of the substrate mycelium, and soluble pigment) is (especially in the case of the genus *Streptomyces*) very useful (Tables 6 and 7; Figs. 3 and 4). Here the traditional methods extensively described by Korn-Wendisch and Kutzner (1992a) are highly recommended.

A microscopic characterization (particularly the morphologies of the aerial mycelium, arthrospores and vegetative mycelium) is of high value (Figs. 7–11). See Korn-Wendisch and Kutzner (1992a) and chapter 3 of Kieser et al. (2000) for details of the methods on microscopy.

Furthermore, the detection of LL-A₂pm in cell wall or whole-cell hydrolysates, the lack of mycolic acids, the predominance of mainly *iso*- and *anteiso*-methyl branched fatty acids, and the 16S rRNA sequence are well suited for genus identification (Table 1).

Identification of Species

Kitasatospora Novel isolates can be readily identified as members of the genus by 16S rRNA gene and 16S-23S rRNA gene spacer analyses. The presence of *meso*-A₂pm in whole cell

hydrolysates is an important chemotaxonomic character for differentiation from *Streptomyces* (Table 1). Additional chemotaxonomic investigations (polar lipids, fatty acid patterns, and menaquinone type) are helpful for allocation of an unknown isolate to the genus. The *meso*-A₂pm content is 49–89% in *Kitasatospora* strains and 1–16% in *Streptomyces* strains (Zhang et al., 1997). Strains belonging to the genus *Streptacidophilus* contain (like *Streptomyces*) LL-diaminopimelic acid as predominant diamino acid (Kim et al., 2003). For further species identification, the characters shown in Table 8 are helpful.

Streptacidophilus Novel isolates can be readily identified as members of the genus by 16S rRNA gene analysis. The presence of LL-A₂pm in whole cell hydrolysates and other chemotaxonomic characters (e.g., polar lipids, fatty acid patterns, and menaquinone type; see family description) are shared by members of the genus *Streptomyces*. The three species of the genus *Streptacidophilus* can be differentiated on the basis of some phenotypic properties (Table 9).

Streptomyces The identification of species poses severe problems. Because of the high number of validly published species (Table 4), most of which are based on a single strain description, it is at present not possible to recommend a single method or even a set of methods for identification at the species level. Because a clear species concept within the genus *Streptomyces* is still pending, investigators should be very careful with species allocations on the basis of the results of one or few methods. The ICSP Subcommittee on the Systematics of Streptomycetaceae (Kämpfer and Labeda, 2003) has recommended that before a species concept of the genus *Streptomyces* is formulated more genomic information should be evaluated, and it was agreed “that the proposal of new species should only be accepted on the basis of very careful studies done with sufficient practice and considering all other species.” In recent years, only a few species have been proposed on the basis of 16S rRNA sequence analysis and phenotypic characterization (most often restricted to those species closely related by phylogenetic analysis [e.g., Boucek-Mechine et al., 2000; Kim et al., 2000; Kim and Goodfellow, 2002a, b; Li et al., 2002a; Li et al., 2002b; Meyers et al., 2003; Petrosyan et al., 2003; Zhang et al., 2003]). The ICSP Subcommittee on the Systematics of Streptomycetaceae (Kämpfer and Labeda, 2003) recommended a careful look at synonymy as a first step to reduce the number of “species” within the genus.

At present two complete *Streptomyces* genomes are available (Omura et al., 2001; Ikeda

From Korn-Wendisch and Kutzner (1992).

et al., 2003). Bentley et al. (2002) reported the first complete genome sequence of *S. coelicolor* and described a model for the evolution of the large linear chromosome, where the central core region contains mostly the essential housekeeping genes and the “arms” contain laterally acquired contingency genes. A comparison of the *S. averiltilis* and *S. coelicolor* genomes supports this model (Bentley et al., 2003). Most of the secondary metabolism gene clusters are located in the arms. The detailed study of genomes of different streptomycetes and housekeeping genes may provide a more reliable basis for an intragenetic subdivision (Stackebrandt et al., 2003).

Ecophysiology and Habitat

The following sections are largely based on the information summarized by Korn-Wendisch and Kutzner (1992a). Members of the family Streptomycetaceae are ubiquitous in nature. Members of the genus *Kitasatospora* have been predominantly isolated from soils (Zhang et al., 1997), and *Streptacidiphilus* species have been isolated from acidic soils and litter (Kim et al., 2003). Streptomycetes can be isolated in high numbers in soil, which is their natural habitat. Most streptomycetes can degrade complex and

^aTaxa are identified as: 1) strain SK-3255^T; 2) strain SK-3406^T; 3) *K. setae* KM-6054^T; 4) *K. phosalacinea* KA-338^T; 5) *K. griseola* AM-9660^T; 6) *K. chochleata* IFO 14768^T; 7) *K. cystarginea* IFO 14836^T; and 8) *K. paracochleata* IFO 14769^T. All strains are positive for peptonization of milk, hydrolysis of starch, and utilization of D-glucose. All strains are negative for liquefaction of gelatin and utilization of inositol and D-mannitol.

Data were from Tajima et al. (2001) for strains SK-3255^T and SK-3406^T, Ōmura et al. (1982) for *K. setae* KM-6054^T, Takahashi et al. (1984b) for *K. phosalacinea* KA-338^T and *K. griseola* AM-9660^T, Nakagaito et al. (1992a) for *K. chochleata* IFO 14768^T and *K. paracochleata* IFO 14769^T and Nakagaito et al. (1992b) for *K. cystarginea* IFO 14836^T. From Tajima et al. (2001).

recalcitrant plant and animal materials, often polymeric residues including polysaccharides (e.g., starch, pectin, cellulose and chitin), proteins (e.g., keratin and elastin), lignocellulose, and aromatic compounds.

Members of the genus *Streptomyces* are involved in the biodegradation of various polymers abundant in soil owing to their ability to produce extracellular enzymes. The biodegradative activities of actinomycetes in general were reviewed in the 1980s by Lechevalier (Lechevalier, 1981a; Lechevalier, 1988), Crawford (1988), and Peczynska-Czoch and Mordarski (1988). Streptomyces are among the very few bacteria able to degrade lignin which occurs in nature

closely associated with cellulose and xylan (hemicellulose), i.e., in the lignocellulose complex. Although fungi play the more important role in lignin decomposition (Crawford, 1981; Crawford, 1988; Janshekar and Fiechter, 1983; Kirk and Farrell, 1987), evidence from experiments using ¹⁴C-labeled lignin now shows that streptomyces (Crawford, 1978; Antai and Crawford, 1981) and also several other genera of actinomycetes are involved in this process (McCarthy and Broda, 1984a; McCarthy et al., 1984b; McCarthy et al., 1986). As a constituent of the lignocellulose complex, cellulose can be degraded by the few ligninolytic streptomyces. More details are given by Ramachandra et al. (1988), Wang et al. (1990),

Crawford et al. (1993), Chamberlain and Crawford (2000), Kormanec et al. (2001), Gottschalk et al. (2003), and Kaneko et al. (2003).

In addition, multicomponent cellulases consisting of several endoglucanases and exoglucanases have been found in thermophilic and mesophilic streptomycetes (Enger and Sleeper, 1965; Crawford and McCoy, 1972; MacKenzie et al., 1984; Schrempf and Walter, 1995; Harchand and Singh, 1997; Marri et al., 1997; Ulrich and Wirth, 1999; Wirth and Ulrich, 2002). Also, xylanases involved in the decomposition of the lignocellulose complex have been found in streptomycetes (Kluepfel and Ishaque, 1982; Kluepfel et al., 1986; Deobald and Crawford, 1987; Godden et al., 1989; Schäfer et al., 1996; Morosoli et al., 1999). Again, xylanases seem to be more widespread among thermophilic actinomycetes (McCarthy et al., 1985). Pectinolytic streptomycetes have been reported (Sato and Kaji, 1975; Sato and Kaji, 1977; Sato and Kaji, 1980a; Sato and Kaji, 1980b) and chitinolytic complexes consisting of chitinase and chitinase have been isolated from various streptomycetes: *Streptomyces griseus* (Berger and Reynolds, 1958), *Streptomyces antibioticus* (Jeuniaux, 1966), and other streptomycetes (Beyer and Diekmann, 1985). For more details, see The Family Streptomycetaceae, Part II: Molecular Biology in this Volume).

The ability to decompose starch (the primary material for the textile, paper and food industry) is widespread among fungi and bacteria. The involved enzymes, amylases, have been detected in various streptomycetes (Mordarski et al., 1970; Suganuma et al., 1980; Fairbairn et al., 1986; McKillop et al., 1986).

In addition to degrading polymeric compounds (as described above), streptomycetes can

play an important role in the destruction of other organic materials used by humans for diverse purposes, among them cotton and plant fibers (Khan et al., 1978; Lacey and Lacey, 1987), wool (Noval and Nickerson, 1959), hydrocarbons in jet fuel and emulsions (Genner and Hill, 1981), and rubber (Cundell and Mulcock, 1975; Hutchinson et al., 1975). The biodeterioration of natural and synthetic substances has been reviewed in detail by Lacey (1988) and Behal (2000). More details are given in The Family Streptomycetaceae, Part II: Molecular Biology in this Volume.

Most isolated streptomycetes are nonfastidious; they do not require organic nitrogen sources or vitamins and other growth factors. Soil as a habitat gives support to their mycelial growth. Furthermore, spore formation enables streptomycetes to adapt to various physical conditions in soil (such as shifts in aeration, moisture tension, and pH), periods of drought, frost, hydrostatic pressure, and anaerobic conditions which may change dramatically and quickly.

The spores can be regarded as a semi-dormant stage in the life cycle that facilitates survival in soil for long periods (Mayfield et al., 1972; Ensign, 1978). Morita (1985) reported viable cultures from 70-year-old soil samples. A relatively high number of streptomycetes in soil is almost always present as inactive spores. The very low germination efficiencies often obtained may be caused by competition with other indigenous microorganisms, but pre-germinated spores are found to grow for a short time and then re-sporulate (Lloyd, 1969a). Germination may depend on the presence of special signaling factors, and there is evidence that exogenous nutrients, water and Ca^{2+} are required (Ensign, 1978). Furthermore the nutrient status of the

germination site influences the extent of hyphal growth and the time to differentiation into aerial hyphae. Many other "habitats" may come into contact with soil owing to human or other activities. As listed by Korn-Wendisch and Kutzner (1992a), these are 1) fodders and other organic material and 2) freshwater and marine habitats as well as potable water systems. Mesophilic and especially thermophilic streptomycetes are involved in the degradation of many natural substrates (e.g., hay, fodder, grain, and wood) and can degrade synthetic products (e.g., cotton textiles, fabric, paper, rubber, plastics and plasticizers). Drainage after heavy rainfalls causes creeks and rivers to become contaminated with soil streptomycetes that find their way into the sediments of freshwater lakes and even to marine biotopes. According to some reports, drinking water supplies may also become contaminated with streptomycetes; some of them produce odorous compounds leading to the spoilage of the water. Streptomycetes play only a minor role as plant pathogens, and although very few streptomycetes have been isolated from pathological material so far, their role as agents of infectious diseases cannot be ignored (more details are given below).

Soil as Habitat

A number of biotic and abiotic properties characterize any habitat and determine the current composition of the community and also the numbers of microorganisms. These are: 1) vegetation and content and kind of organic matter, 2) soil type, 3) season and climate, 4) temperature, 5) circulation of water and air, and 6) pH. As already pointed out by Korn-Wendisch and Kutzner (1992a), the reports published on the occurrence of streptomycetes in soil are numerous and too extensive to be treated quantitatively. The reader is referred to reviews by Lechevalier (Lechevalier, 1981a; Lechevalier, 1988), Williams (1982a), Goodfellow and Williams (1983), Williams et al. (1984b), Goodfellow and Simpson (1987a), Korn-Wendisch and Kutzner (1992a) and to a series of papers by Williams and coworkers dealing specifically with the ecology of actinomycetes in various soils and under specific conditions: Davies and Williams (1970), Williams and Mayfield (1971b), Williams et al. (Williams et al., 1971c; Williams et al., 1972; Williams et al., 1977), Mayfield et al. (1972), Ruddick and Williams (1972), Watson and Williams (1974), Khan and Williams (1975), Flowers and Williams (1977), Williams and Robinson (1981). By direct observation of the soil microflora, several authors have shown that streptomycetes perform their typical life cycle in this natural habitat. For details of this life cycle and its genetic control, the reader is referred

to Kieser et al. (2000). As summarized by Korn-Wendisch and Kutzner (1992a), in most soils, 10^4 to 10^7 colony forming units (CFU) per g can be expected, accounting for about 1–20% of the total viable count; in some soils however streptomycetes dominate. The number of streptomycetes and also the number of subgroups vary under different conditions. Details can be found in the studies of Flaig and Kutzner (1960a), Misiek (1955), Szabó and Marton (1964), and Küster (1976).

Note that the detection and localization of different *Streptomyces* species or types in their natural habitat are based mainly on cultivation dependent techniques. In addition, the difficulties in the intrageneric classification of the genus *Streptomyces* often do not allow a comparison of these ecophysiological studies. With respect to moisture, it has been shown by Williams et al. (1972) that streptomycetes resist desiccation because they form arthrospores. In addition they need a lower water tension for growth than other bacteria need, but they may be very sensitive to water-logged conditions.

Most streptomycetes prefer neutral to alkaline soils as a natural habitat (e.g., Flaig and Kutzner, 1960a). But several studies of acidic soils employing media adjusted to acid pH and supplemented with antifungal agents found numerous acidophilic as well as acid-tolerant streptomycetes. Khan and Williams (1975), Hagedorn (1976), and Williams et al. (1977) showed in detail that acidic forest soils and other acidic habitats contained different groups or species of streptomycetes. These streptomycetes also have unusual properties when compared with neutrophilic strains, e.g., production of specific amylases (Williams and Flowers, 1978b) and chitinases (Williams and Robinson, 1981). Only a few reports of alkalophilic, acid-sensitive actinomycetes have been published (Taber, 1959; Taber, 1960; Mikami et al., 1982; Mikami et al., 1985).

Streptomycetes, like other soil bacteria, may also be found in the intestinal tract of earthworms (Brüsewitz, 1959; Parle, 1963b; Parle, 1963a), the gut of arthropods (Szabó et al., 1967; Bignell et al., 1980; Bignell et al., 1981; Bignell, 1984), and the pellets produced by millipedes and woodlice (Márialigeti et al., 1984).

Studies on the occurrence of streptomycetes in the rhizosphere have been published by various authors (for a review, see Goodfellow and Williams, 1983). The competitive advantage of antibiotic-producing organisms over nonproducing microbes in soil has been suggested since the time these compounds were first discovered. However, evidence for the in situ production of antibiotics in soil is still not clear (Williams, 1982a). This may be due to 1) the instability and low concentrations in soil (Brian, 1957; Williams,

1982a) and 2) possible adsorption to soil colloids in combination with inadequate and insensitive detection methods (Williams, 1982a) and 3) the ephemeral growth of producers in response to nutrient shortage (Williams and Khan, 1974; Williams, 1982a).

However, Rothrock and Gottlieb (1984) reported antibiotic production occurs in sterilized soil supplemented with nutrients and inoculated with a potent producer. Many soil microbiologists support the assumption that streptomycetes play an important role in the control of fungal root pathogens (Williams, 1978a; Williams, 1982a; Sing and Mehrotra, 1980; Rothrock and Gottlieb, 1981). In addition many streptomycetes are often successful in competition with other rhizosphere bacteria such as pseudomonads and bacilli, especially in relatively dry soil.

Thermophilic Streptomycetes

The genus *Streptomyces* contains mainly mesophilic species in addition to some thermotolerant (growing up to 45°C) and a few thermophilic species. A detailed taxonomic study of thermophilic streptomycetes has been published by Kim et al. (1999). Additional thermophilic species (*S. thermocoprophilus* and *S. thermospinisporus*) have been described by Kim et al. (2000) and Kim and Goodfellow (2002b). The thermophilic streptomycetes described so far grow at 28–55°C, and several grow at even higher temperatures.

Thermophilic streptomycetes go through an interesting cycle in nature in regard to their dispersal: active growth takes place at sites of high temperature such as in compost, manure, and self-heating hay or grain. The vegetative phase ends with the formation of a large number of spores. These are returned with the compost or manure to the fields and pastures where they infect plant material and hay directly or via soil dust (Korn-Wendisch and Kutzner, 1992a). Not surprisingly, the majority of actinomycetes isolated from bioaerosols in the surroundings of composting facilities belong to the genus *Streptomyces* (P. Kämpfer et al., unpublished observation). For this reason thermophilic actinomycetes are widespread and can be isolated from various sources like soils (Tendler and Burkholder, 1961; Craveri and Pagani, 1962), pig feces (Ohta and Ikeda, 1978), sewage-sludge compost (Millner, 1982), and freshwater habitats (Cross, 1981).

Freshwater Environments, Water Supplies and Marine Environments

Actinomycetes can easily be isolated from fresh water and especially from sediments of rivers

and lakes. Cross (1981) stated, however, that most of these organisms may not be active at these sites. Nevertheless, these wash-in forms (“aliens”) from surrounding terrestrial environments can survive as dormant spores in aquatic habitats for a long time (Al-Diwany and Cross, 1978), and especially rivers carry a load of various actinomycetes, among them also streptomycetes. In a study on the occurrence of actinomycetes in the river Thames, Burman (1973) found 59–200 streptomycetes per ml and 10–20 micromonosporae per ml. These organisms were found to grow on decaying vegetation on riverbanks and mud flats at low water or on floating mats of decaying algae or other vegetation. Under these conditions odorous substances are produced, and subsequent increase in river levels washes them into the water, thus giving rise to “earthy taste” complaints. Of these odorous compounds, geosmin and methyl iso-borneol are most often detected (Gerber, 1979a; Gerber, 1979b). As summarized by Wood et al. (1983), the prevention of earthy tastes in reservoirs and water supply systems depends on locating the production sites and determining the patterns of distribution of these compounds (Silvey and Roach, 1975; Lechevalier et al., 1980).

Burman (1973) studied the fate of actinomycetes of river water in the course of production of drinking water. Filtration processes reduce the number of streptomycetes considerably. In the distribution system, a new type named “aquatic strains of *Streptomyces*” has appeared, which can be enriched (for details, see Burman, 1973).

Okazaki and Okami (1976), Cross (1981), Weyland (1981b), Weyland (1981a), Weyland and Helmke (1988), and Goodfellow and Haynes (1984) have reviewed the occurrence of streptomycetes in marine habitats including sediments. Two localities can be distinguished: 1) the littoral and inshore zone and 2) deep-sea sediments. From both localities streptomycetes can be isolated; however, similarly to streptomycetes in freshwater environments, most of these organisms are “survivors” rather than constituents of the autochthonous microflora. From the littoral zone, streptomycetes have been isolated both from sediments (Roach and Silvey, 1959) and from decaying seaweed (Siebert and Schwartz, 1956). These isolates were able to grow on polymeric substances, e.g., agar and chitin (Humm and Shepard, 1946), alginate and laminarin (Chesters et al., 1956), and cellulose (Chandramohan et al., 1972), characteristic for these microsites.

In sediments, both the depth and location of sample sites play important roles in determining the ratio of different taxa of actinomycetes (Weyland, 1981b; Weyland and Helmke, 1988). Sites in the open sea generally contain only low

numbers of actinomycetes (viable counts were about 100 CFU per ml of wet sediment). The distribution (horizontal as well as vertical) is assumed to correlate with the physiological properties of the three taxa *Streptomyces*, *Micromonosporae* and *Rhodococci barotolerance* (Helmke, 1981), halotolerance, and psychrophilism (Weyland, 1981a). Goodfellow and Haynes (1984), however, were not able to find a correlation between salinity, pH, or depth and the number of actinomycetes recovered from marine sediments. In this study numerous isolates are described in detail, and from a total of 732 organisms, 250 belonged to *Streptomyces*, 250 to *Micromonospora*, 140 to *Rhodococcus*, and 92 to *Thermoactinomyces*. A selected number of isolates belonging to the genus *Streptomyces* was subsequently identified using 41 diagnostic tests and applying the MATIDEN program and the *Streptomyces* probability matrix (Williams et al., 1983b). Around 50% of these streptomycetes were similar to those grouped into cluster 1 of Williams et al. (1983a).

Okami and Okazaki (1978) found streptomycetes (300–1270 colonies per cm³) mainly in the sediments of shallow seas (70–520 m deep), whereas in samples 700–1600 m deep, *Micromonospora* dominated. No actinomycetes were obtained from depths of 2800 and 5000 m in the Pacific Ocean. A higher salt tolerance of marine streptomycetes than of their terrestrial counterparts was observed. However, already Tresner et al. (1968) found that salt tolerance among streptomycetes is widespread and this feature may be due to selection of the more tolerant organisms in marine habitats. Few streptomycetes isolated from marine environments were found to be obligate halophiles (Okazaki and Okami, 1976).

Notably, marine habitats are essential for screening programs in the search of new antimicrobial and anti-insecticidal compound producers. In early studies, Nissen (1963) found a high percentage of antibiotic-producing streptomycetes from decaying seaweed, and subsequent investigations confirmed these findings (Okami and Okazaki, 1972; Okami et al., 1976; Hotta et al., 1980).

Isolation

The procedures of isolation of streptomycetes (extensively summarized by Korn-Wendisch and Kutzner, 1992a) are partly summarized in the next paragraphs. Additional information about isolation for special purposes, growth of streptomycetes, and preservation of streptomycetes can be obtained from the excellent textbook *Practical Streptomyces Genetics* (Kieser et al., 2000).

Generally, all procedures for the isolation of microorganisms are influenced by the nature of the microorganism and the number of propagules relative to the number of other microbes within the habitat (Stolp and Starr, 1981). If the organism to be isolated is best adapted to the selected isolation conditions, then direct plating of a serial dilution on a nutrient agar medium can readily lead to a pure culture. This procedure does not work well for isolation of streptomycetes. These actinomycetes are isolated usually by enrichment or use of selective media and specific isolation conditions or both.

As already pointed out by Korn-Wendisch and Kutzner (1992a), Streptomycetaceae members can be isolated using general selective isolation procedures (Williams and Wellington, 1982b; Williams and Wellington, 1982c; Williams et al., 1984a). These procedures require 1) choice of the material containing the selected microorganisms, 2) pretreatment of the sample, and in some cases, enrichment of the chosen microbial groups, 3) use of selective media or selective incubation conditions or both, and 4) colony selection on the basis of colony morphology and purification.

Streptomycetes can be isolated from a wide variety of habitats, and most isolation procedures involve extraction from soil or another environmental sample followed by dilution of the cells (cell aggregates) to allow cultivation on solid media.

Isolation and Enrichment from Soil

Because the vegetative mycelium and spore chains are often closely associated with the mineral and organic particles of the soil, vigorous shaking of the sample with the diluent is often needed to suspend the spores of mycelial fragments. Use of glass beads and agitation on a shaker may aid suspension. In the literature, methods involving mechanical devices such as the Ultrasonics sonicator-disrupter, Ultra-Turrax homogenizer, Turmix blender, Waring blender, or a mortar and pestle are described, but a detailed comparison of the dilution efficiency of these pretreatments is still missing. Chemical disruption methods are also reported in literature. Gently shaking soil samples with an ion-exchange resin Chelex-100 (Biorad) followed by differential centrifugation and filtration was used to separate the mycelium from the spores (Herron and Wellington, 1990).

A subsequent treatment of samples (i.e., preparing dilutions and plating) differs little from general bacteriological practice. Most often the coarse particles of the soil suspension are allowed to settle before dilutions are made. But soil particles may also be used directly for incu-

bation of "soil plates" (Warcup, 1950), which are also used to isolate fungi. The addition of lime to soil can enrich for streptomycetes (see chapter 2 of Kieser et al. [2000] and references therein). Isolation plates may be surface-inoculated with a sterile glass rod (or Drigalski spatula).

Spread of motile bacteria via water films can be avoided by drying the plates at 45°C before incubation or mixing the soil suspension with the molten agar, which is highly recommended (Korn-Wendisch and Kutzner, 1992a). The addition of CaCO₃ to air-dried soil samples (10:1 w/w) and subsequent incubation at 26°C for 7–9 days in a water-saturated atmosphere can lead to a 100-fold increase of streptomycete colonies on isolation plates (Tsao et al., 1960; El-Nakeeb and Lechevalier, 1963).

The enrichment of streptomycetes by soil amendment with keratin was first carried out by Jensen (1930). Later the addition of chitin to soil was found to stimulate growth of actinomycetes (Williams and Mayfield, 1971b). Williams and Robinson (1981) similarly obtained the enrichment of acidophilic and neutrophilic streptomycetes in acidic soil and litter containing pure and fungal chitin. Another isolation strategy using chitin in the form of insect wings has been used as a baiting method (Veldkamp, 1955; Jagnow, 1957; Okafor, 1966). Porter and Wilhelm (1961) studied isolation using various other organic materials, like salmon viscera meal, peanut meal, cottonseed meal, and dried blood flour (15 mg/g of soil). They found that incubation of the enrichment cultures under moist conditions led to an up to 1000-fold increase in the number of streptomycetes.

Besides the frequently used arginine glycerol agar (El-Nakeeb and Lechevalier, 1963), the following media (details below) are also often applied for selective isolation of streptomycetes: HV agar (Hayakawa and Nonamura, 1987a, 1987b), colloidal chitin agar (Hsu and Lockwood, 1975), and reduced arginine starch salts agar.

Several physical, chemical and biological methods have been studied to reduce or inhibit other microbes (for review, see Goodfellow and Williams, 1986a). Nüesch (1965) centrifuged soil suspensions for 20 min at 1600 × g to separate the spores of streptomycetes (in the supernatant) from other bacteria and spores of fungi (in the sediment); however, the method has not been very successful. Using a similar approach, El-Nakeeb and Lechevalier (1963) obtained a significantly smaller number of streptomycete colonies as compared with the control. Voelskow (1988/1989) described a simple sedimentation method in which 1 g of soil was suspended in 15 ml of salt solution, vigorously shaken, and then treated with ultrasonic vibrations. After 1, 2, and 4 h of sedimentation, samples were taken

from different levels of this solution, further diluted, and plated on agar surfaces.

Initial drying and heating procedures were applied because arthrospores have a relatively high resistance to low moisture tension. Drying of the sample or prolonged storage at ambient temperatures for mesophiles and at 50–60°C for thermophiles led to a relative increase in streptomycete concentrations. Williams et al. (1972) showed that heat treatment of soil (40–50°C, 2–16 h) leads to a significant reduction of the vegetative bacterial proportion without affecting the colony counts of streptomycetes.

Membrane filtration has been mainly used for the enrichment of streptomycetes from water samples (Burman et al., 1969) and from seawater and mud (Okami and Okazaki, 1972), but it has also been a first step in the isolation of streptomycetes from soil (Trolldenier, 1966). These authors used 1 ml of a series of 10-fold dilutions, which were membrane-filtered (0.3-µm pore size). This filter was then placed upside down on a suitable agar medium, which was supplemented with 10% compost soil. Colonies developed between the agar surface and the membrane filter, and the streptomycetes (but not other bacteria or fungi) were able to grow through the pores. Using this method, the selective effects of the physical barrier (the membrane) and the soil lead to a 3–5-fold increase in the number of streptomycete colonies in comparison with poured plates without soil.

Hirsch and Christensen (1983) introduced the use of cellulose ester membrane filters (pore size 0.01–3.0 µm), which were placed onto nutrient agar containing antifungal antibiotics (cycloheximide and candidin). These plates were inoculated with different samples from soil, water and vegetable materials. After 4 days, the hyphae of actinomycetes penetrated the filter pores and grew on the underlying agar medium, whereas the growth of the other bacteria was restricted to the surface of the filter. To allow further development of actinomycete colonies, the membrane filter was removed and the plates were reincubated. Filters (0.22–0.45 µm) were also found to be suitable for the exclusive recovery of actinomycetes. Polsinelli and Mazza (1984) and Hanka et al. (1985) used this approach independently.

Several authors have added chemicals to improve the isolation efficiency. Phenol treatment of a dense soil suspension (1.4% for 10 min) was recommended to eliminate bacteria and fungi, but El-Nakeeb and Lechevalier (1963) obtained less favorable results with this method. Chloramine, ammonia, and sodium hypochlorite were mainly employed for the treatment of water samples, because it has been found that streptomycetes and other actinomycetes are

slightly more resistant to these agents than other bacteria are (Burman et al., 1969).

Isolation of Airborne Spores

For the isolation of *Streptomyces* spores from self-heating material such as hay or compost, samples can be agitated in a wind channel (Lacey and Dutkiewicz, 1976b) or sedimentation chamber (see below; Lacey and Dutkiewicz, 1976a). Plates are then inoculated with the aerosol using an Andersen sampler (Goodfellow and Williams, 1986a). This method, widely employed for the isolation of thermophilic actinomycetes, may also be used for the isolation of mesophilic streptomycetes from soil.

In addition, other devices like filtration samplers (e.g., Sartorius MD 8) are suitable for the sampling of airborne streptomycetes.

Use of Selective Media and Incubation

Selective media always play an important role in the isolation of the desired microorganisms. A number of factors can be varied: 1) nutrient composition and concentration of the isolation medium, i.e., choice of carbon and nitrogen sources preferred by the organisms; 2) addition of chemical substances to inhibit selectively the accompanying flora of the natural habitat or those which are stimulating the desired organisms; 3) pH, for acidophilic, neutrophilic, and alkalophilic organisms; and 4) temperature, e.g., for the isolation of thermophiles or psychrophiles.

Many different media have been formulated empirically and proposed for the isolation of streptomycetes. Selected carbon and nitrogen compounds listed in Table 10 are especially suitable for the isolation of these organisms. The

most frequently used media with their formulas are listed in Tables 11 and 12. Alternatively, streptomycetes can be grown on very poor media such as water agar.

DIFFERENT CARBON AND NITROGEN SOURCES FOR ENRICHMENT Because it was early recognized that streptomycetes can degrade chitin (Veldkamp, 1955; Jagnow, 1957), a chitin medium was devised by Lingappa and Lockwood (1962) for selective isolation. However, the authors and later also El-Nakeeb and Lechevalier (1963) found that their chitin agar was only a little better than water agar. Hsu and Lockwood (1975) added mineral salts to this medium (Table 11), which was shown to be useful for the isolation of actinomycetes (*Streptomyces*, *Nocardia* and *Micromonospora*) from water samples but had little effect when isolating actinomycetes from soil. Note that chitinolytic activity is not a genus specific feature for streptomyces. Williams et al. (1983a) found that only 25% of over 300 strains were strongly chitinolytic, so this widely used medium selects the chitinolytic streptomycete strains, which may not be the most abundant strains in soil. Starch is degraded by the vast majority of streptomycetes and can therefore be used as a selective carbon source. An early finding was that the combination of starch with nitrate, which is utilized by many streptomycetes (in contrast to other bacteria) as nitrogen source, is very useful for the selective isolation of streptomycetes (Flaig and Kutzner, 1960a). Küster and Williams (1964), who improved this medium, stated: "The three best media, allowing good development of streptomycetes while suppressing bacterial growth, were those containing starch or glycerol as the carbon source with casein, arginine or nitrate as the nitrogen source."

Table 10. Nutritional substances and selective agents for isolation of streptomycetes from soil (according to Korn-Wendisch and Kutzner, 1992).

Table 12. Composition of some media suitable for the cultivation of streptomycetes.^a

Ingredients		Comments
1. Glucose-yeast extract-malt extract (GYM) agar		
Glucose	4.0g	Addition of CaCO ₃ (2.0g/liter) is advantageous for the growth of many streptomycetes. Adjust pH to 7.2.
Yeast extract	4.0g	
Malt extract	10.0g	
Agar	12.0g	
Distilled water	1 liter	
2. Oatmeal agar		
Oatmeal	20.0g	Cook 20.0g of oatmeal in 1 liter of distilled water for 20min. Filter through cheesecloth. Add distilled water to restore the volume of the filtrate to 1 liter, then add trace salts solution and agar. Adjust pH to 7.2.
Agar	12.0g	
Trace salts solution (see no. 5)	1.0ml	
Distilled water	1 liter	
3. Inorganic salts-starch agar		
Starch (soluble)	10.0g	Make a paste of the starch with a small amount of cold distilled water and bring to a volume of 1 liter; then add the other ingredients. Adjust pH (if necessary) to 7.0–7.4.
(NH ₄) ₂ SO ₄	2.0g	
K ₂ HPO ₄ (anhydrous basis)	1.0g	
MgSO ₄ ·7H ₂ O	1.0g	
NaCl	1.0g	
CaCO ₃	2.0g	
Trace salts solution (see no. 5)	1.0ml	
Agar	12.0g	
Distilled water	1 liter	
4. Glycerol-asparagine agar		
Glycerol	10.0g	The pH should be about 7.0–7.4. Do not adjust if it is within this range.
L-Asparagine (anhydrous)	1.0g	
K ₂ HPO ₄	1.0g	
Trace salts solution (see no. 5)	1.0ml	
Agar	12.0g	
Distilled water	1 liter	
5. Trace salts solution		
FeSO ₄ ·7H ₂ O	0.1 g	
MnCl ₂ ·4H ₂ O	0.1g	
ZnSO ₄ ·7H ₂ O	0.1g	
Distilled water	100.0ml	
6. Trace elements solution SPV-4		
CaCl ₂ ·2H ₂ O	4.0g	SPV-4 is used as an alternative to (5). Five ml of this stock solution is added to 1 liter of medium.
Fe (III) citrate	1.0g	
MnSO ₄	0.2g	
ZnCl ₂	0.1g	
CuSO ₄ ·5H ₂ O	0.04g	
CoCl ₂	0.022g	
Na ₂ MoO ₄ ·2H ₂ O	0.025g	
Na ₂ B ₄ O ₇ ·10H ₂ O	0.1g	
Distilled water	1 liter	

^aRecipes 1–5 are from Shirling and Gottlieb (1966) and recipe 6 from Voelskow (1988/89).

From Korn-Wendisch and Kutzner (1992).

Benedict et al. (1955) were the first to report that the combination of glycerol and arginine favored streptomycete isolation. El-Nakeeb and Lechevalier (1963) found that this medium (Tables 11 and 12) was superior to nine other media, resulting in higher number and proportion of streptomycete colonies.

Other compounds (e.g., pectin [Wieringa, 1955], poly- β -hydroxybutyrate [Delafeld et al., 1965], rubber [Nette et al., 1959], cholesterol [Brown and Peterson, 1966], elemental sulfur [Wieringa, 1966], and natural and artificial humic acids [Hayakawa and Nonomura, 1987a, 1987b]) have been used successfully, and most of them

strongly select certain organisms producing visible zones of clearing or other changes in the medium.

The use of compounds with antifungal activity (antibiotics) as supplements to isolation media has also been widely used to suppress fungal growth (Table 10). The most frequently used compound is cycloheximide (actidione, 50–100 µg/ml) by Williams and Davies (1965). Pimaricin and nystatin (each 10–50 µg/ml) were found to be even more effective (Williams and Davies, 1965).

The use of compounds with antibacterial activity is more restricted because actinomycetes are often also sensitive to them. Williams and Davies (1965) found polymyxin (5 µg/ml) and penicillin (1 µg/ml) suppressed bacterial flora; however, they also inhibited streptomycetes. Preobrazhenskaya et al. (1978) showed that the genera of Actinomycetales may differ significantly in their sensitivity to antibacterial antibiotics and that streptomycetes were the most sensitive group. Thus, the use of antibacterial compounds may be more helpful in isolating other genera of this order (Cross, 1982).

In contrast, some antibiotics may facilitate the isolation of certain species or groups of *Streptomyces*. For example, the selective isolation of members of the *Streptomyces diastaticus* cluster sensu Williams et al. (1983a) was achieved on starch casein medium containing rifampicin (50 µg/ml; Vickers et al., 1984). Wellington et al. (1987) found a similar effect with several media containing different C and N sources as well as with media supplemented with inhibitors.

Hanka et al. (1985) described a selective isolation medium for streptoverticil-producing *Streptomyces* species containing cycloheximide and nystatin (each 50 g/ml, to control fungal growth) and oxytetracycline (25 µg/ml, to suppress other actinomycete genera and other *Streptomyces* groups). Hanka and Schaadt (1988) enhanced selectivity of this medium by adding lysozyme (1000 µg/ml). Also, sodium propionate can suppress the competing fungi (Crook et al., 1950; Table 11), and Rose Bengal (35 mg/liter) in starch casein nitrate agar (Ottow, 1972) can suppress most of the bacteria and inhibit the spreading growth of fungi.

pH OF THE ISOLATION MEDIUM AND INCUBATION TEMPERATURE Most streptomycetes grow optimally at neutral pH values, i.e., are neutrophilic. Therefore, the pH of most isolation media is 7.0–7.5. However, for the isolation of acidophilic streptomycetes, the medium pH is 4.5 (Khan and Williams, 1975), and for alkalophilic strains, it is 10–11 (Mikami et al., 1982). Most streptomycetes isolated from soils are mesophilic, and therefore plates are most often incubated at 22–

37°C (mostly at 28°C). Psychrophilic strains (e.g., from marine environments) grow at 15–20°C. In contrast, thermotolerant and thermophilic representatives can be isolated at higher temperatures (40, 45, 50, or 55°C). Note that thermophiles often form colonies after a short period of incubation (within 2–5 days), and mesophilic members produce visible colonies within 7–14 days. However, marine and other psychrophilic organisms often need several weeks (up to 10) for the formation of visible colonies.

Colonies of *Streptomyces* are in most cases readily recognized by their macroscopic and microscopic appearance. In most cases, *Streptomyces* are easily purified by picking colonies and transfer to a nonselective medium. According to Williams and Wellington (1982b), purification is “undoubtedly the most time-consuming and often the most frustrating stage of the isolation procedure.” Acidiphilic members of the Streptomycetaceae can be isolated on acidified starch casein agar containing cycloheximide and nystatin (Kim et al., 2003).

Isolation of Antibiotic Producers and Strains for Genetic Studies

The isolation of antibiotic producing streptomycetes follows the same procedures as given above. Most often, the activity is tested after isolation of pure cultures, but this can also be combined with the isolation procedure. Thus, strains exhibiting antibiotic activity can be recognized even on the initial dilution plates if they are treated with an appropriate test organism, either by flooding or by spraying. Zones of inhibition can be detected after further incubation (Lindner and Wallhäuser, 1955; Wilde, 1964). As an alternative, a simple replication procedure allows the examination of the antibiotic activity of the colonies against selected sensitive organisms (Lechevalier and Corke, 1953). Selective techniques for isolation and screening of actinomycetes that produce antibiotics and other secondary metabolites of clinical relevance have been summarized by Nolan and Cross (1988). In addition, Kieser et al. (2000) have provided a set of protocols for selective isolation of streptomycetes, generating spore suspensions, and several other more sophisticated procedures.

Isolation of Thermophilic Streptomycetes

As already stated, thermophilic streptomycetes and other thermophilic actinomycetes are often isolated from samples derived from high temperature environments (e.g., compost materials, manure heaps, and fodders). The high temperatures (45–60°C) can serve as a selective condition

that favors enrichment of the desired organisms (Festenstien et al., 1965).

As pointed out by Greiner-Mai et al. (1987), a very important requisite for the isolation of thermophilic streptomycetes is a humid atmosphere, which can be achieved by incubating plates in large jars with water in the bottom. Alternatively, the sealing of Petri dishes with masking tape is also effective.

Interestingly, the media recommended for the isolation of thermophilic actinomycetes, including streptomycetes, contain higher nutrient concentrations than those used for mesophilic strains. In addition, antifungal agents and antibacterial agents are sometimes added as supplements (Lacey and Dutkiewicz, 1976b; Goodfellow et al., 1987c). For some special isolation techniques, the reader is referred to the papers of Uridil and Tetrault (1959), Fergus (1964), Gregory and Lacey (1963), and Cross (1968). Additional information can be obtained from the publications of Kim et al. (Kim et al., 1996; Kim et al., 1998; Kim et al., 2000).

Isolation from Aquatic Habitats

For the isolation of streptomycetes from water, the media listed in Table 11 can be used. In a comparative study on the suitability of media, Hsu and Lockwood (1975) found that chitin-agar was superior to the other four (egg albumin, glycerol arginine, starch casein, and *Actinomyces* isolation agar; see also Table 11).

Water samples can be directly streaked onto the solid medium after dilution. When low numbers are expected, the samples can be concentrated by membrane filtration (for details, see Burman et al. [1969] or Trolldenier [1967]).

Streptomycetes from marine habitats were successfully isolated on media containing 25 or 75% seawater (Weyland, 1981a; Weyland, 1981b), artificial seawater (Goodfellow and Haynes, 1984), or deionized water supplemented with 3.0% NaCl (Okami and Okazaki, 1978). For further details, see also Weyland (1981b) and Goodfellow and Haynes (1984).

Isolation from Infected Plants

For the isolation of streptomycetes from diseased plant tissue (i.e., from scabby potato or beet surface layers), three general steps have been recommended (see also Korn-Wendisch and Kutzner, 1992a): 1) sterilization of the surfaces of tubers, beets, or roots; 2) maceration of the plant tissues; and 3) use of appropriate media for plating.

Methods for isolating *Streptomyces scabies* from potatoes have been described in detail by several authors (Taylor, 1936; KenKnight and

Munzie, 1939; Menzies and Dade, 1959; Adams and Lapwood, 1978; Archuleta and Easton, 1981).

Cultivation

Nutritional Requirements and Media for Sporulation

The vast majority of streptomycetes are nonfastidious organisms, having a chemoorganotrophic metabolism. The nutritional requirements are (in most cases) restricted to an organic carbon source (e.g., starch, glucose, glycerol and lactate) and an inorganic nitrogen source (NH_4^+ or NO_3^-), in addition to the essential mineral salts for growth. The necessity to amend media with specific trace elements has not been studied in detail. Many of the early used media (even the “synthetic” media) were not supplemented with trace elements, although the positive effect of trace elements in soil on the growth of streptomycetes has been reported (Spicher, 1955). Other authors used quite different recipes (Tables 11 and 12), each containing only a select number of metal ions. A rather complete mixture (SPV-4; Table 12) has been found to be optimal for actinomycetes and other bacteria (Voelskow, 1988/1989).

Because no specific requirement for vitamins or organic growth factors has been described, “synthetic media” can be used for their cultivation. Notably, complex organic substrates (e.g., oatmeal, yeast extract, or malt extract) are well utilized and enhance growth rates and biomass production. A combination of a complex organic carbon source with a single amino acid as nitrogen source (e.g., glutamic acid, arginine or asparagine) is also suitable.

Several authors have proposed “general media” for streptomycetes that allow the completion of the streptomycetes’ life cycle, i.e. germination of spores, growth of substrate and aerial mycelium, and formation of spores (visible because of the typical color of the spores). Some of these media have been used in the International *Streptomyces* Project (ISP). Of the great number of useful media (Pridham et al., 1956/1957), four are of particular value and most often used (Table 12). Additional media are listed by Waksman (1961) and by Williams and Cross (1971a). CaCO_3 added to some media not only supplies Ca^{2+} for growth but also neutralizes acids produced by many streptomycetes. These media also allow good sporulation. Because macroscopically heavy aerial mycelia may contain very few spores and aerial mycelia hardly detectable by the naked eye may be a good source of spores, it is advisable to check these cultures microscopically. Specialized media,

especially for genetic studies, are given by Kieser et al. (2000).

Media Containing Soil, Clay, Minerals and Calcium Humate

Addition of soil to isolation media increases the number of colonies as it promotes growth, sporulation and pigmentation (Trolldenier, 1966). Martin et al. (1976) observed the stimulation of both growth and metabolic activity of some actinomycetes when montmorillonite or Ca-humate was added to a liquid medium. A similar effect was observed for clay in dialysis tubes after a short lag period, which was explained by a possible adsorption of one or more inhibitory substances produced during growth. Martin et al. (1976) also reported a positive effect of these adsorbing materials on the genetic stability of other bacteria and on fungi.

Temperature and Oxygen

As pointed out above, most streptomycetes are mesophilic organisms; however, psychrophilic as well as thermotolerant and thermophilic species are also known. Note that in many instances, the optimum temperature for fast growth or maximal yield may not be the best choice for studying the production of secondary metabolites (e.g., antibiotics and pigments). Most streptomycetes have an obligately aerobic metabolism, but many streptomycetes are able to reduce nitrate to nitrite under strictly anaerobic conditions.

In semisolid agar with a nutrient medium, they grow at the surface of the agar column; however, in semisolid agars with a poor medium or non-utilizable carbon source, they grow microaerophilically. A stationary liquid culture grows as a pellicle at the surface, and the medium remains completely clear.

Cultivation and Preparation of Inoculum

For subcultivation and maintenance, and for most diagnostic tests, streptomycetes are preferably cultivated on solid media in dishes or slants. On solid media many strains produce aerial mycelia and spores when the entire surface is covered by confluent growth. Since *Streptomyces* colonies, in contrast to most molds, spread over a limited distance, a point inoculation will often not lead to a confluent growth.

Some strains show sporulation only when the plates are cross-hatched inoculated, i.e., by a method which leaves empty spaces between the streaks. Sporulation generally occurs better under dry conditions. For this reason, slants should be incubated horizontally for the first two days to allow the liquid to soak into the surface

of the agar (Hopwood et al., 1985). The starting material should be a suspension of inoculum in liquid (Kieser et al., 2000).

The propagation of cultures by successive rounds of mass culture should be avoided, but instead a single colony should be picked and streaked to start the next culture. Especially in genetic studies, this reduces the accumulation of revertants or the gradual loss of selected plasmids or both (Kieser et al., 2000).

Note that morphological heterogeneity is often observed when streptomycetes are cultivated on solid media (for more details, see Kieser et al., 2000).

Because it may be difficult to produce a homogeneous suspension from the grown colonies (a prerequisite for inoculation of some diagnostic tests; Kämpfer et al., 1991b), precultivation in liquid media is sometimes useful. This is the case for certain physiological studies (e.g., degradation tests), for the provision of cell material for biochemical analysis, and for the production of secondary metabolites (e.g., antibiotics) or enzymes. For these purposes, streptomycetes can be cultivated in liquid medium with agitation.

The use of liquid cultures started from an inoculum of spores is also recommended for many detailed studies, e.g., for preparation of protoplasts for fusion, transformation or transfection.

Notably, the multicellular lifestyle of streptomycetes complicates the study of metabolic properties, where all cells of the initial suspension should be in the same physiological condition. In general, streptomycetes grow by mycelial elongation and branching. But when central parts of the colony become nutrient limited, physiological homogeneity cannot be sustained. To overcome these problems, spore germlings are used for physiological studies, even though a large amount of spores is needed. Other solutions include liquid cultures supplemented with dispersants, like sucrose, polyethylene glycol, Junlon®starch, agar and carboxymethylcellulose. Chapter 2 of Kieser et al. (2000) summarizes the advantages and disadvantages. Since streptomycetes are highly aerobic, the cultures need to be shaken during incubation. Use of Erlenmeyer flasks with indentations or stainless steel springs is recommended, but for small quantities (3–5 ml being enough for some physiological tests), tubes in a slanted position on a shaker or roller also allow excellent supply of oxygen. Note that some secondary metabolites (e.g., antibiotics and pigments, which are produced on solid media) may fail to be synthesized under these conditions.

Korn-Wendisch and Kutzner (1992a) recommend two media that have been widely used for the submerged cultivation of streptomycetes (g/liter): 1) GPYB broth (glucose, 10.0; peptone from casein, 5.0; yeast extract, 5.0; beef extract,

5.0; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.74; pH 7.2) and 2) soybean meal-mannitol nutrient medium (soybean meal, 20.0; mannitol, 20.0; pH 7.2). Two kinds of inoculation material can be employed for subculturing streptomycetes: 1) arthrospores and 2) vegetative mycelium, occasionally including "submerged spores" (Wilkin and Rhodes, 1955). Kieser et al. (2000) recommend similar procedures.

Spore suspensions can be used over a period of several weeks when stored at 4°C, but since the spores tend to settle and clump, the addition of a few glass beads to the screw-cap tube helps to resuspend the spores before use. Chapters 8 and 9 of Kieser et al. (2000) describe the preparation of mycelia for detailed DNA or RNA studies.

Preservation

Several different procedures have been employed for the short- and long-term preservation of microorganisms (Kirsop and Snell, 1984).

Three short-term preservation methods have been described by Korn-Wendisch and Kutzner (1992a). First, agar slope cultures may be stored at 4°C for few months. Second, spore suspensions can be mixed with soft water agar and kept at 4°C (Kutzner, 1972). And third, glycerol can be added to spore suspensions (final concentration, 10%, v/v) and stored at -20°C (Wellington and Williams, 1978); these cultures (after thawing) can serve as inoculum for most diagnostic tests except carbon utilization (Williams et al., 1983a). Kieser et al. (2000) recommended for long-term preservation the preparation of a spore suspension in 20% glycerol and freezing at -20°C. Another procedure is the growth of strains in complex media (like trypticase soy broth [TSB] agar), addition of 20% glycerol plus 10% lactose, and storage in the vapor phase of liquid nitrogen. In addition, drying on unglazed porcelain beads (Lange and Boyd, 1968), followed by soil culture (Pridham et al., 1973), and lyophilization (Hopwood and Ferguson, 1969) are used. For longer preservation (see The Family Nocardioptaseae in this Volume), spore suspensions or homogenized mycelia are mixed with glycerol to a final concentration of 25% and kept at 25°C (Wellington and Williams, 1978). Alternatively, spores and mycelia suspended in 10% skim milk are lyophilized. A very simple, reliable, and time-saving method is liquid nitrogen cryopreservation of living cells in small polyvinyl chloride (PVC) tubes ("straws") at -196°C. The procedure has been tested for various actinomycetes. The strains are harvested from well-sporulated cultures grown on suitable agar media in Petri dishes. A 2 × 25-mm piece of sterile PVC tubing is pressed into the mycelial mat

and agar and carefully raised to excise the agar plug. This is repeated until the tube is filled with agar. The filled tubes are placed in a sterile cryovial (the screw cap marked with the strain accession number). A 1.8-ml vial will hold up to 13 tubes. Two vials are prepared for each strain and then fixed to a metal clamp for freezing in the gas phase of a liquid nitrogen container. After 10–15 min, when temperature falls below -130°C, the clamp can be immersed in the liquid phase at -196°C. A container with a capacity of 250 liters will hold at least 8000 vials or 4000 strains. For viability testing, one tube is removed from the vial within the nitrogen gas atmosphere of the container and placed directly and thawed on a suitable agar medium. After a few days incubation, the mycelium will be visible. For those strains that do not produce an abundant mycelium, the plugs may be pushed out of the tubes by a sterile needle.

Detection of *Streptomyces* Using Cultivation-independent Methods

Microorganisms in the environment can be identified without cultivation by retrieving and sequencing macromolecules and using oligonucleotide probes (largely based on small subunit rRNA; Amann et al., 1995; Rappé and Giovannoni, 2003). Stackebrandt et al. (1991b) developed 16S rRNA-targeted oligonucleotide probes specific for certain *Streptomyces* species and subsequently studied bacterial diversity in a soil sample from a subtropical Australian environment (Stackebrandt et al., 1993). They found that most sequences were from alpha subclass Proteobacteria and only a few from streptomycetes. Hahn et al. (1992), using the in situ hybridization approach, were unable to analyze bacterial populations in soil without prior activation by adding nutrients. Growing cells, e.g., *Streptomyces scabies* hyphae, were easily detected. The use of specific primers in connection with environmental clone libraries is a powerful approach for study of the microbial diversity in soil (Felske et al., 1997; Rheims et al., 1999; Rintala et al., 2001; Courtois et al., 2003) and discovery of novel bioactive metabolites (Donadio et al., 2002). More details are given in The Family Streptomycetaceae, Part II: Molecular Biology in this Volume.

Acknowledgments. The basis of the sections on ecophysiology, isolation and habitats has been the excellent and comprehensive treatise of Korn-Wendisch and Kutzner (1992a) from the second edition of *The Prokaryotes*, which is still recommended for deeper study of classical approaches in *Streptomyces* biology.

The Family Streptomycetaceae, Part II: Molecular Biology

HILDGUND SCHREMPF

Introduction

Some members of the order of Actinomycetales were already identified about a century ago (for review, see Kutzner, 1981). The current phylogenetic tree includes Bifidobacteriaceae, Actinomycetaceae, Arthrobacteriaceae, Cellulomonadaceae, Microbacteriaceae, Dermathophilaceae, Propionobacteriaceae, Nocardiodaceae, Frankiaceae, Corynebacteriaceae, Mycobacteriaceae, Nocardiaceae, Actinoplanaceae, Pseudonocardiaceae, Streptomycetaceae and Streptosporangiaceae.

The family Streptomycetaceae includes the genus *Streptomyces*, which comprises strains formerly classified as *Chania*, *Elytrosporangium*, *Kitasatoa*, *Kitasosporia*, *Actinosporangium* and *Streptoverticillium*. All members of the Streptomycetaceae family have a complex life cycle, featuring an extended vegetative substrate mycelium and aerial hyphae, in which spores form upon depletion of nutrients. They contain specific menaquinones, incorporate LL-diaminopimelic acid (a diagnostic amino acid) into their peptidoglycan, but lack a diagnostic sugar (Kutzner, 1981). In addition they contain characteristic signatures within the genes for 23S and 16S rRNA (Roller et al., 1992; Embley and Stackebrandt, 1994). An enormous number (>800) of *Streptomyces* species has been described by numerical taxonomy (Goodfellow et al., 1990). Kämpfer presents the current methods for classification in another chapter, The Family Streptomycetaceae, Part I: Taxonomy, in this Volume.

Sixty years ago, streptomycin was the first antibiotic which was classified from a *Streptomyces* strain. Since then, streptomycetes have proved to be the richest sources of thousands of low-molecular weight, chemically different compounds having antibacterial, antifungal, antiparasitic, agro-active, cytostatic or other biological activities. Additionally, they have provided many enzymes which are required for the natural turnover of many macromolecules in soil.

As outlined in this chapter, the tools of molecular biology in combination with physiological,

biochemical, and genetic studies have considerably deepened understanding of the biology of streptomycetes. This knowledge is the current and future basis for exploiting the seemingly endless repertoire of metabolites and activities of the family of Streptomycetaceae.

The Developmental Growth Cycle

Growth Characteristics

Streptomycetes grow by tip extension as long, branching vegetative hyphae, which rarely have septae. The compartments within the substrate hyphae contain numerous copies of the chromosomal DNA. Aerial hyphae begin to form upon depletion of nutrients. The aerial structures contain several surface layers. One of them is the hydrophobic rodlet layer, which comprises the proteins RdlA and RdlB. The corresponding genes within *Streptomyces coelicolor* A3(2) and *S. lividans* are expressed within growing aerial hyphae but not within spores (Claessen et al., 2002). Partitioning of the chromosomes occurs within the aerial hyphae, in which a comparatively synchronous septation entails the formation of compartments, resulting in the formation of spores after maturation. Each of the spores (or the majority of them) contains a single chromosome. Using fusions of the gene of interest with the gene for green fluorescent protein (GFP), the distribution of the corresponding fusion protein can be visualized during development (Flardh, 2003).

Bald (*bld*) mutants lack aerial mycelia and thus have a shiny (bald) appearance. In addition to the block in differentiation, *bld* mutations lead to pleiotrophic effects, which often cause defects in carbon catabolite repression and cell-cell signaling and sometimes prevent antibiotic production. Whereas most *bld* genes within *S. coelicolor* A3(2) determine regulatory proteins, *bldK* can encode a transporter for an extracellular peptide. *BldA* specifies a tRNA for a rare codon and *bldN* determines a member of the extracytoplasmatic function subfamily of RNA polymerase sigma factors. During differentiation, the pro-sigma

BldN-form is processed to the mature Bld (Bibb and Buttner, 2003). As expected *S. coelicolor* A3(2) and *S. griseus* share several orthologous genes which are important for the development of the aerial hyphae (Chater and Horinouchi, 2003). The genes *ramC* and *ramR* are required for the production of the aerial hyphae, yet are not essential for vegetative growth. The production of RamC requires developmental regulatory genes (*bldD*, *crpA* and *ramR*, but not *bldN* and *bldM*; O'Connor et al., 2002).

The action of different *whi* (white) genes induces a curling of the aerial hyphae, their septation, and finally spore formation. Early regulatory *whi* genes (*A*, *B*, *G*, *H*, *I* and *J*) from *S. coelicolor* A3(2) are needed for septation during sporulation and the *whiA* gene plays a key part in switching the extension of aerial hyphae towards septation (Ainsa et al., 2000). The genome of *S. coelicolor* A3(2) encodes about 60 sigma (σ) factors. A subfamily of nine σ factors controls late sporulation, and σ^H is involved in the development of aerial hyphae (in addition to responses to various stresses), whereas spore maturation is governed by σ^F .

Bacterial cell division is initiated by the polymerization of the FtsZ protein on the inner surface of the cytoplasmatic membrane to form the Z-ring structure at the future division site (Lutkenhaus, 1997; Margolin, 2003). FtsZ is a homologue of tubulin and interacts with several proteins of auxiliary functions (i.e., Z-ring anchoring, stabilization and others). Transcription studies in *S. griseus* have suggested that *ftsZ* is expressed during both vegetative growth and sporulation (Dharmatilake and Kendrick, 1994). The *S. coelicolor* A3(2) FtsZ is required for septation within the vegetative substrate mycelium as well as for the synchronous formation of septae within the developing aerial hyphae prior to the detectable partitioning of nucleoids (Grantcharova et al., 2003).

The differentiation cycle generally occurs on solid media, although some strains (i.e., *S. griseus*; McCue et al., 1996) synchronously undergo sporulation in liquid culture. Recently differentiation of *S. coelicolor* A3(2) has been demonstrated in standing liquid minimal media (Van Keulen et al., 2003). Interestingly, gas vesicles are present within hyphae at the air interface of standing liquid culture. *Streptomyces coelicolor* A2(3) has been shown to contain a gene cluster encoding proteins resembling gas vesicles of cyanobacteria and their homologues within halophilic archaea.

Several *Streptomyces* strains show a transient slow down during growth in liquid culture before entering the stationary phase. This transition phase is characterized by an increase in ppGpp (guanosine 3', 5'-bispyrophosphate), by a

decrease in GTP, as well as by the activation of genes required for secondary metabolism. The synthesis of two ribosomal proteins is drastically reduced when the culture approaches the stationary phase (Blanco et al., 1994).

Autoregulating Factors

Autoregulating factors form during the late stage of growth, presumably under the control of global regulatory systems. These autoregulating compounds (Khokhlov et al., 1967; Horinouchi and Beppu, 1992) have a 2,3-disubstituted σ -butyrolactone skeleton in common. They have been classified into three groups: the A-factor type (*S. griseus*), virginiae butanolide (VB) type (*S. virginiae*), and IM-2 type (*S. spec.* FRI-5). Although the structural differences among the butyrolactones are slight, each of them is effective at very low concentrations (10^{-9} M). Their mode of action resembles that of a highly specific hormone or morphogen for a given strain, controlling the formation of various secondary metabolites (such as antibiotics and pigments), as well as the formation of aerial mycelium. Presumably, a given σ -butyrolactone is also an effective chemical signal for communication between different parts of the mycelium within one strain (Horinouchi and Beppu, 1992). The receptor proteins ArpA, BarA and IM2 deduced from the corresponding genes (*arpA* in *S. griseus*, *barA* in *S. virginiae*, and *farA* in *Streptomyces spec.* FRT-5) share an NH₂-terminally located helix-turn-helix (HTH) motif and each includes a binding domain with high specificity for the respective ligand. Recent studies suggest that ArpA and BarA represent transcriptional regulators recognizing a specific DNA motif, and it was suggested that they prevent the expression of certain key gene(s) during the early growth phase before a critical level of the corresponding ligand is reached. Upon binding to the ligands, the key gene(s) for secondary metabolites and morphogenesis are transcribed. Like ArpA, CprB from *S. coelicolor* A3(2) acts as a negative regulator and affects actinorhodin formation and sporulation. In contrast, the second *S. coelicolor* A3(2) homologue, CprA, is a positive regulator accelerating synthesis of secondary metabolite(s) and sporulation (Onaka et al., 1998).

Accumulating evidence reveals that a pair (or sometimes multiple pairs) of genes encoding a probable γ -butyrolactone biosynthetic enzyme (an AfsA-like protein and its specific receptor ArpA-like protein) is contained in a number of biosynthetic gene clusters for secondary metabolites in various *Streptomyces* species. It controls the biosynthesis of respective metabolites by activating pathway-specific regulatory genes (Horinouchi, 2002).

Geosmin, Storage Compounds, and Exopolysaccharides

Geosmin (1, 10-*trans*-dimethyl-*trans*-9-decalol) is the characteristic odor constituent of streptomycetes. Its synthesis is initiated by cyclization of farnesyl diphosphate to a germacradiene-type intermediate (Spiteller et al., 2002).

Under a range of conditions which allow sporulation, glycogen accumulates in sporogenic hyphae and is presumably converted into trehalose during the final period of spore maturation (Rueda et al., 2001). The operon required for glycogen-trehalose metabolism within *S. coelicolor* A3(2) has been characterized (Schneider et al., 2000).

Triacylglycerols (TAG) are fatty acid triesters of glycerol which are abundant in yeast, fungi, plants and animals and have also been found in bacteria. They do, however, seem to be widespread and vary in composition among actinomycetes including species of *Streptomyces*, *Rhodococcus*, *Nocardia* and *Mycobacterium*. Poly-3-hydroxybutyric acid (PHB) has been detected within different *Streptomyces* strains (Verma et al., 2002). A gene cluster encoding for exopolysaccharide formation has recently been identified within a *Streptomyces* strain (Wang et al., 2003).

Chromosomal DNA

Structure and Genomic Information

Most *Streptomyces* strains contain a large genome. On the basis of genetic studies, a circular genome was concluded to be present in *S. coelicolor* A3(2). Ordered cosmid libraries in combination with comparisons of physical maps from the wildtype and mutant strains of *S. coelicolor* A3(2) and *S. lividans* lead to the deduction that the chromosome occurs in a linear and in a circular form (Lin et al., 1993; Redenbach et al., 1996). Pulse-field gel electrophoresis (PFGE) studies revealed the existence of a linear chromosome in other streptomycetes, including *S. ambofaciens* (Leblond et al., 1996), *S. antibioticus*, *S. moderatus*, *S. lipmanii*, *S. parvulus*, *S. rochei* (Lin et al., 1993), *S. griseus* (Lezhava et al., 1995) and *S. hygroscopicus* (Pang et al., 2002). Linear topology of the chromosomal DNA has been demonstrated for a *Streptoverticillium* sp. belonging to the family of Streptomycetaceae and for representatives of other actinomycetes, including *Actinoplanes philipinensis*, *Nocardia asteroides*, *Saccharopolyspora erythraea* (Redenbach et al., 1998) and *Rhodococcus fascians* (Crespi et al., 1992). In this context, it is interesting that genomes of different *Myco-*

bacterium sp. were found to be circular (Philipp et al., 1996).

The *S. coelicolor* A3(2) linear chromosome comprises about 8.667 mega base pairs (Mbp) from which 7825 genes can be deduced. Twenty gene clusters encode known or predicted secondary metabolites (Bentley et al., 2002). Recently the *S. avermitilis* genome was determined to comprise about 9.025 Mbp (average G+C content 70.7 mol%) and to encode 7574 potential open reading frames, 35% of which constitute 721 paralogous families. Thirty gene clusters could encode secondary metabolites. One region of 6500 Mbp has been highly conserved with respect to gene order in the *S. avermitilis* and *S. coelicolor* A3(2) genomes and contains predicted essential genes. However the terminal regions are not conserved and preferentially contain nonessential genes (Ikeda et al., 2003). An ancient synteny (conservation of gene-order) has been revealed between the central core of the *S. coelicolor* A3(2) chromosome and the whole chromosome of *Mycobacterium tuberculosis* and *Corynebacterium diphtheriae* (Bentley et al., 2002).

Initiation of DNA Replication and Terminal Repeats

The structure of the chromosomal replication origin (*oriC*) region is highly conserved among the investigated *Streptomyces* strains *S. coelicolor* A3(2) (Calcutt and Schmidt, 1992), *S. lividans* (Zakrzewska-Czerwinska and Schrempf, 1992), *S. ambofaciens*, *S. antibioticus*, *S. chrysomallus* and *S. reticuli* (Jakimowicz et al., 1998). Contrary to the high overall G+C content (69–73 mol%) of *Streptomyces* DNA, the *oriC* region is comparatively rich in A+T (64 mol%) and contains 19 DnaA boxes (consensus sequence TTGTCCACA) arranged in two clusters (134 bps). Thus, interactions between DnaA molecules may bring two clusters of DnaA boxes separated by the spacer into functional contact by loop formation (Jakimowicz et al., 2000). The *oriC* of *S. lividans* and *S. coelicolor* A3(2) is located centrally, opposite the terminal ends located in the formerly designated “silent region” of the chromosome. EshA (a 52-kDa protein whose expression is developmentally controlled) forms during the late growth phase. It has been proposed that the *S. griseus* EshA protein positively affects (or regulates) the replication of DNA in wildtype cells during the late growth phase but leads to aberrant phenotypes in mutant cells owing to disturbed DNA replication (Saito et al., 2003).

The chromosomal ends of a few *Streptomyces* species contain terminal inverted repeats (TIRs) covalently bound to protein, presumably at their

5'-ends. Depending on the strains, the length of the TIRs varies between 20 kb and 550 kb. They have a considerable sequence-divergence except for the first, about 200 bps comprising palindromic sequences. Modeling predicts that the 3'-ends of these sequences can form extensive hairpin structures resembling those characterized within the 3'-ends of the single-stranded parvoviral DNA. Most of the putative hairpins contain a GCGCAGC-sequence able to form a single C-residue loop closed by a sheared G:A base pair. As the *Streptomyces* chromosome is replicated from the centrally located replication origin, 3'-single-stranded gaps arise which are assumed to be patched by an unknown mechanism involving the covalently bound terminal proteins (TP; Huang et al., 1998). The *tpgC* gene encodes the TP (TpgC) protein of the *S. coelicolor* A3(2) genome and is predicted to have a DNA-binding motif (which is found in reverse transcriptase) and an amphiphilic domain, possibly involved in protein-protein interactions or membrane-binding. Whereas one chromosomal *tpg* gene has been found in *S. coelicolor* A3(2) and *S. rochei*, three homologues are present within the *S. lividans* chromosome (Bao and Cohen, 2001; Yang et al., 2002). The TPs (about 185 amino acids) of *Streptomyces* form a conserved group that is divergent from those of linear genomes of bacteriophages (i.e., Φ , PRD1) and viruses (i.e., adenoviruses, 600–660 amino acids) or eukaryotic linear plasmids. Recent results indicate that the Tap protein functions to recruit and position the Tpg protein at the telomers of replication intermediates (Bao and Cohen, 2003).

Deletions and Amplifications

Among colonies—or sectors of colonies—of *Streptomyces* species, a high spontaneous variability of pigmentation, sporulation, antibiotic biosynthesis, or A-factor production is noticeable. Several unstable genes encode various antibiotic resistances, A-factor formation, and synthesis of tyrosinase or arginosuccinate. Genetic instability can be stimulated by mutagens including mitomycin, ethidium bromide, and ultraviolet light and by gyrase- (topoisomerase II) inhibiting antibiotics. These variations are the result of large chromosomal deletions which occur preferentially at the telomeric and subtelomeric regions and may include up to 2 Mbp of DNA (Hütter and Eckhardt, 1988; Schrempf et al., 1989; Leblond and Decaris, 1994; Chen, 1995). Deletions may occur in high frequencies (up to 10^{-2}), in several cases sequentially at either one or both ends of the chromosome. Concomitantly, amplification(s) of amplifiable unit(s) of DNA (AUD) may occur.

In some cases, amplifications of certain genes correlate with enhanced levels of gene products. Accordingly, the 4.3-kb AUD (*S. lividans*) encodes a surface-located protein which is overexpressed in large quantities after amplification (Betzler et al., 1997). Upon selection for high resistance towards spectinomycin (Hornemann et al., 1986) or chloramphenicol (Dittrich et al., 1991), variants comprising amplifications of the corresponding gene have been encountered. Moreover, it has been suggested (Qin and Cohen, 2002) that spontaneous circularization of linear chromosomes may be the consequence of telomere damage that cannot be repaired by homologous recombination. An *S. lividans* mutant deficient in the *recR* gene that encodes one of the proteins of the RecF pathway (Pelaez et al., 2001) segregates a large portion of small colonies, the majority of which fail to produce aerial mycelium. Many of them are nonviable or have chromosomal deletion(s) including the chloramphenicol resistance gene. The RecA protein within different *Streptomyces* species is larger than the corresponding one of other bacteria as it contains an extra long C-terminus (Ahel et al., 2002).

The variability of the chromosomal DNA is increased by its interaction with linear and circular plasmids, phages, transposons, and insertion-elements (see below). As streptomycetes inhabit quickly changing environments (see below), those variants that are best adapted are expected to rapidly multiply. The high plasticity of the genome is likely an effective prerequisite for quick adaptation.

Repetitive DNA (mostly insertion-sequences or directly repeated GC-elements) is used for the efficient classification of mycobacterial strains (Kamerbeek et al., 1997). Comparative investigations of genomic sequences have permitted the deduction of additional diagnostic elements for mycobacteria (Philipp et al., 1996). Comparative strategies are expected to facilitate in future the classification *Streptomyces* strains.

Plasmids, Transposons, and Phages

Circular Plasmids and Their Vector Derivatives

In addition to the chromosomal DNA, *Streptomyces* strains contain various types of circular plasmids of different sizes. The low-copy number circular plasmid SCP2 was the first one to be isolated from a streptomycete (Schrempf et al., 1989). Despite its relatively large size, it is used as a cloning vector. The plasmid SCP2* (a variant of SCP2; Hopwood et al., 1985) has recently been sequenced and deduced to encode 34 pro-

teins, most of them lacking similarity to known ones. The replication region contains the *repI* and the *repH* genes encoding small proteins. While the *traA* gene is essential for DNA transfer and pock-formation, 10 additional genes are suspected to be involved in conjugation and DNA spreading. Among them are genes required for plasmid stability. The *ParA* gene product shows similarity to a family of ATPases (Haug et al., 2003).

The natural plasmid pIJ101 (about 8.8 kb) is a high-copy number conjugative *Streptomyces* plasmid. Regions required for its replication, stability, transfer and distribution have been identified. Efficient conjugation among streptomycetes necessitates the plasmid-encoded *tra* gene and the *cis*-acting locus of transfer (*clt*; Ducote et al., 2000). A variety of nonconjugative derivatives carrying a selectable marker have been constructed (Hopwood et al., 1985). The derivative pIJ702 (5.8 kb), containing a tyrosinase and a thiostrepton-resistance gene, has been frequently used as a vector. After *in vitro* mutagenesis, a derivative of pIJ702 exhibiting a temperature-sensitive replication phenotype has been selected. Several *Escherichia coli*-*Streptomyces* bifunctional vectors have been constructed using derivatives of pIJ101. However, some of them are not particularly stable. Nonetheless, pWHM3 and pWHM4 (Vara et al., 1989) have been used successfully for gene cloning.

The plasmid pSG5 (initially found in *Streptomyces ghanaensis*) is 12.3 kb, is naturally temperature-sensitive, and cells contain approximately 50 copies per chromosome. A number of vectors, several of them bifunctional, have been constructed using pSG5. The replicon of pSG5 is naturally temperature-sensitive. All vectors based on this replicon can be eliminated easily at nonpermissive temperatures and can be used as suicide delivery systems (see below) for transposons (Baltz et al., 1997) as well as for gene disruption and gene replacement experiments (Muth et al., 1995). A pSG5-based cosmid vector has been shown to be transferable to a *Micromonospora aurantia* strain by intergeneric conjugative transfer (Rose and Steinbuchel, 2002).

The multicopy plasmids pSN22 (Kataoka et al., 1991), pJV1 (Bailey et al., 1986) and pSMA2 (Pernodet et al., 1984) replicate via a rolling circle mechanism (Hagege et al. 1993; Servín-González, 1993). All Rep proteins encoded by these plasmids carry at their N-terminus a motif resembling zinc fingers found also in DNA topoisomerase I or other unwinding proteins. The deduced Rep protein (Muth et al., 1995) of pSG5 differs from the above-mentioned ones insofar as it is most closely related to one of the pC194 family in other Gram-positive bacteria.

The 11-kb pSMA2 (initially identified within *S. ambifaciens*) occurs in an autonomous form and is subject to rolling circle DNA replication. The pSMA2 plasmid is self-transmissible and mobilizes chromosomal markers. Specific recombination with the chromosomal *attB* attachment site requires the pSMA2-encoded integrase; the plasmid can stably integrate or can subsequently re-excite. Replicase, excisionase, and integrase genes constitute an operon that is positively regulated by the regulator gene *pra* (Sezonov et al., 1998). Recent studies have suggested that during conjugation, pSMA2 is transferred as double-stranded DNA, depending on the presence of the plasmid-located *trasA2* gene. Notably, TraSA (Possoz et al., 2001) shows similarities to other *Streptomyces* plasmid transfer proteins but also with SpoIIIE involved in chromosome partitioning into the prespore in *Bacillus subtilis* and the *E. coli* FtsK involved in movement of double-stranded DNA. Replicative and integrative vectors using pSMA2 were constructed.

Linear Plasmids

Although linear plasmids are abundant among streptomycetes, only some of their encoding functions have been identified. These include antibiotic production (Kinashi et al., 1991; Gravius et al., 1994) and mercury resistance (Ravel et al., 1998). Some linear plasmids are efficiently transferred during conjugation. The *tra* genes of the linear plasmid pBL1 have been characterized by insertional inactivation (Zotchev and Schrempf, 1994). Among the features common to all linear plasmids are terminal inverted repeats of varying length and the presence of a terminal protein, the latter being linked to the 5'-ends as shown for SCP1 (*S. coelicolor* A3(2); Kinashi et al., 1991) or pSLA2 (*S. rochei*; Hirochika et al., 1984). The linear plasmid pHZ6 (70 kb) residing within *S. hygroscopicus* is a temperature-sensitive replicon, representing a hitherto unique feature among known natural linear plasmids (Pang et al., 2002).

The replication mechanism is best understood for pSLA2. In contrast to the linear φ *Bacillus* phage DNA, its replication is initiated bidirectionally near the center and proceeds towards its telomeric ends, generating 3' leading-strand overhangs. The basic replicon (1.9 kb) contains the information required for autonomous replication in the circular form (Hiratsu et al., 2000). The 21-kDa terminal protein (Tpg) of pSLA2 had been isolated. Its gene encodes a protein with a reverse transcriptase-like domain. Interestingly, homologues of the *tpgR* gene are located on other linear plasmids or chromosomes (see above). As shown for *S. lividans* (Chen, 1995) and *S. rimosus* (Gravius et al.,

1994), large linear plasmids can interact with the ends of the chromosome.

The SLP1 (int) element (17.2 kb) specifically integrates into the *S. coelicolor* A3(2) chromosome. During mating with *S. lividans*, SLP1 (int) can excise and form a family of autonomously replicating conjugative plasmids (Hagege et al., 1999). SLP2 (50 kb) is a linear *S. lividans* plasmid that contains short terminal repeats and covalently bound terminal proteins. The right most part (15.4 kb) of SLP2 is identical to the *S. lividans* chromosome. The plasmid encodes many genes predicted to be involved in replication, partitioning, conjugational transfer, and intramycelial spread. Though the two telomers differ in their sequence, they retain similar secondary structures (Huang et al., 2003).

Interestingly, several other members of the order of Actinomycetales harbor genes required for isopropylbenzene and trichlorethylene catabolism (*Rhodococcus erythropolis*; Kebeler et al., 1996), biphenyl degradation (*Rhodococcus erythropolis* and *Rhodococcus globerulus*; Kosono et al., 1997), hydrogen autotrophy (*Rhodococcus opacus*, formerly *Nocardia opaca*; Kalkus et al., 1993) and fasciation in plants (*Rhodococcus fascians*; Crespi et al., 1992) on linear plasmids. Linear plasmids of varying sizes have also been discovered in several *Mycobacterium* species (*M. xenopi*, *M. branderi*, *M. celaturnum* and *M. arium*). Their termini are related to those of linear plasmids from *Streptomyces* and *Rhodococcus* species (Picardeau and Vincent, 1998). Exploring whether the linear and circular plasmids are exchanged during conjugation among various actinomycetes should be of interest.

Transposons

Compared to other bacteria, relatively little knowledge exists for *Streptomyces* transposons. A truncated copy of Tn4811 of *S. lividans* is present at the terminal inverted repeats of the *S. coelicolor* A3(2) giant linear plasmid SCP1 (Spychaj and Redenbach, 2001). The transposon Tn4556 was discovered in *Streptomyces fradiae* and used for transposition studies (Chung and Crose, 1989; Ikeda et al., 1993). Tn4560 (8.6 kb) is a derivative of Tn4556, a Tn3-like element from *Streptomyces fradiae*. It contains a viomycin resistance gene and its usefulness as a mutagenesis tool within *Mycobacterium smegmatis* was demonstrated by transformation of this host via a delivery plasmid (Bhatt et al., 2002). On the basis of the *S. lividans* insertion element IS493, transposons containing an antibiotic resistance gene have been developed which are suitable for transposon mutagenesis of various *Streptomyces* strains (Baltz et al., 1997). The IS6100 element

(originally identified in *Mycobacterium fortuitum*; Martin et al., 1990) belonging to the IS6 family normally forms a cointegrate as the end-product of transposition. The IS6100-based mini-transposon Tn1792 has been developed as a genetic tool. The resolution of Tn1792 cointegrates within *S. avermitilis* has facilitated the isolation of insertion mutants and the subsequent rescue of Tn1792-tagged sequences. Subsequently, genes involved in the production of secondary metabolites have been identified (Pitman et al., 2002). An engineered derivative of the *E. coli* transposon Tn5 also transposes randomly into the *S. lividans* genome (Volf and Altenbuchner, 1997).

Phages

As outlined previously, phages of broad or narrow host range can be gained easily from soil and several of them have been used for classifying strains (for review, see Kutzner, 1981).

The *Streptomyces* temperate phage ϕ 31 has a relatively broad host spectrum. It has been revealed that the ϕ C31 receptor is glycosylated. The *S. coelicolor* A3(2) gene encoding the homologue to dolichol-phosphate-mannose synthase is essential for phage sensitivity (Cowlshaw and Smith, 2002). Also, ϕ 31 has a linear genome (41.5 kb) with 3' overhanging cohesive ends (Lomovskaya et al., 1980). The integrase from ϕ C31 is a member of the serine recombinase family of site-specific recombinases. The integrase recombines an attP site in the phage genome with a chromosomal attB site of its *Streptomyces* host (Combes et al., 2002). Thus, ϕ 31 has been used to develop cloning and integration vectors as well as cosmids (Hopwood et al., 1985).

The transducing phages (DAH2, DAH4, DAH5 and DAH6) have been shown to transduce multiple chromosomal markers at frequencies ranging from 10^5 to 10^9 per plaque-forming unit. The host range comprises distantly related species including *S. coelicolor* A3(2), *S. veticillius* and *S. avermitilis* (Burke et al., 2001).

Role of Secreted Proteins

Recognition and Hydrolysis of Polysaccharides

Streptomycetes play a very important role in the turnover of chitin, the second most abundant polysaccharide in nature. Contrary to other chitinolytic bacteria, almost every *Streptomyces* species uses chitin not only as a carbon but also as a nitrogen source (Blaak and Schrempf, 1995). The few analyzed *Streptomyces* strains produce several chitinases (Robbins et al., 1988;

Miyashita et al., 1991). Some of the chitinase genes were cloned, and the corresponding *Streptomyces* transformants secreted the corresponding enzymes. The efficient degradation of crystalline forms of chitin is dependent on the presence of a chitin-binding domain in a chitinase (Blaak and Schrempf, 1995). During growth on chitin, many streptomycetes secrete, in addition to chitinases, small proteins (Kolbe et al., 1998) that act as an adhesive, mediating a biofilm-like contact between chitin-containing substrates or organisms.

Enzymes catalyzing the hydrolysis of soluble forms of cellulose have been investigated for a few *Streptomyces* strains (including *S. lividans*) and cloning of several corresponding genes has been carried out (Crawford and McCoy, 1972; Kluepfel et al., 1986; Nakai et al., 1988). *Streptomyces reticuli* specifically adheres to crystalline cellulose via a membrane-anchored protein (Walter et al., 1998) and efficiently degrades crystalline forms of cellulose to forms of cellobiose (Schlochtermeyer et al., 1992), which serve as nutrients.

The synthesis of amylases and their inhibitors is common among streptomycetes. Some of the genes have been cloned (Virolle and Bibb, 1988) and studies pertaining to a better understanding of the regulation of the glucose-repressed genes have been initiated (Nguyen et al., 1997). Sequence information suggests that the *S. coelicolor* A3(2) genome has many genes for glucosyltransferases. Those belonging to family 13 are predicted to encode starch-converting enzymes.

Xylan consists of a β -1-4-linked xylose polymer and commonly contains side branches of arabinosyl, glucuronosyl, acetyl, uronyl and mannosyl residues. Enzymes degrading this complex polymer have been used for different purposes, including biopulping and biobleaching in the paper industry and bioconversion. Xylanases and their genes were identified from *S. lividans* (Pagé et al., 1996), *S. halstedii* (Ruiz-Arribas et al., 1998), and the thermophilic *S. thermoviolaceus* (Tsujibo et al., 1997). Laccases including those produced by *S. cyameus* can be efficiently applied for biobleaching of kraft pulps (Arias et al., 2003).

Various *Streptomyces* strains produce enzyme inhibitors including allosamidine (chitinase inhibitor), isoflavone (Lee and Lee, 2001), gentisin (α -glucosidase inhibitor) and tendamistat (amylase inhibitor).

Proteases

Extracellular proteases are abundant among streptomycetes, and several corresponding genes have been characterized (Kim and Lee, 1995). Streptomycetes also contain a multitude

of genes for protease inhibitors (Taguchi et al., 1995) including leupeptin and subtilisin (Hiraga et al., 2000). Keratinases are frequently encountered (for review, see Kutzner, 1981), as exemplified by the identification of keratinolytic proteinases in *S. pactum* catalyzing the extracellular reduction of disulfide bonds in the disintegration of chicken feathers (Böckle and Müller, 1997).

Lipases

The interest in bacterial lipases has increased considerably. However, only a few extracellular lipases and their genes have been characterized from *Streptomyces* strains (Servín-González et al., 1997; Sommer et al., 1997). A member of the family II of lipolytic enzymes secreted by *S. rimosus* has been characterized (Vujaklija et al., 2002).

Modification of Various Compounds

Streptomyces strains are dominant among isolates of latex rubber-degrading actinomycetes (Jendrossek et al., 1997). The average weight of synthetic rubber showed shifting to lower values after incubation with degrading *Streptomyces* strains. As diketone derivatives of oligo (*cis*-1,4) isoprene were identified, an oxidative pathway by β -oxidation has been suggested (Bode et al., 2001). Recently, genes involved in the rubber degradation have been identified from a *Micromonospora aurantiaca* strain (Rose and Steinbuchel, 2002).

Streptomycetes produce, in addition to enzymes that degrade macromolecules, a large repertoire of enzymes, including those for the modification of pharmacologically relevant compounds and xenobiotics (Peczynska-Czoch and Mordarski, 1988).

Secretion of Enzymes and Proteins

As in other bacteria, secretion of many proteins depends on the Sec pathway (Morosoli et al., 1999). Type I signal peptidases (SPases) are responsible for proteolytic cleavage of secreted proteins. The *S. lividans* chromosome has four adjacently located *sip* genes encoding functional SPases (Geukens et al., 2001). *Streptomyces lividans* harbors, as do several other bacteria, a functional twin-arginine translocation (Tat) pathway (Schaerlaekens et al., 2001) for folded proteins.

Streptomyces lividans has been shown to be a suitable host for the secretion of proteins, including enzymes (Geueke and Hummel, 2003) and homologous and heterologous proteins (Lammertyn and Anné, 1998).

General Metabolism

Transport Systems

Streptomycetes secrete a variety of enzymes (see above) that hydrolyze complex macromolecules, and the resulting low molecular weight compounds can frequently serve as carbon sources and in some cases (i.e., degradation-products of chitin, see above) as nitrogen sources. Some of the nutrients are taken up via a specific type of an ATP-binding cassette (ABC) transporter, which comprises a lipid-anchored, specific ligand-binding protein, interacting efficiently with either cellobiose and cellotriose, or chitobiose and *N*-acetylglucosamine, maltose, or others. In addition to specific membrane-bound permeases for each type of these transporters, the required ATP-binding protein can be shared by several transporters (Schlösser et al., 1997; Wang et al., 2002; Xiao et al., 2002). The genomic sequences of *S. coelicolor* A3(2) predict the presence of a large diversity of ABC transporters, most of which still require investigation with regard to ligand-specificity. Phosphoenolpyruvate (PEP) dependent phosphotransferase (PTS) uptake has been demonstrated for *N*-acetylglucosamine (Xiao et al., 2002) as well as for fructose. Interestingly, only very few PTS systems can be predicted from genomic sequences: An analysis of the *S. coelicolor* A3(2) genome has indicated the presence of genes encoding components of the PTS systems including permeases belonging to the mannitol-glucose and the glucose-sucrose family (Parche et al., 2000).

Homologous conventional ion transport systems can be deduced from genomic information, but they have not yet been investigated. However, a *Streptomyces* gene for a potassium ion channel (named KscA) has been identified. The functionally reconstituted KcsA protein carries the basic features of a eukaryotic potassium ion channel. Because of its small size, it has become a key model system for understanding the basic features of channel functioning (Schrempf et al., 1995; Meuser et al., 2001).

Streptomycetes have different types of transport systems for antibiotics, few of which have been analyzed with biochemical methods (Dittrich et al., 1991; Méndez and Salas, 1998; Gandlur et al., 2004), and genes for predicted transporters are frequently located within clusters for antibiotic biosynthesis (see below, the section Pharmacologically Active Substances).

Pathways of Primary Metabolites

Knowledge of primary metabolism within streptomycetes is relatively limited. Genes encoding key enzymes, which include fructose

1,6-bisphosphate aldolase and glucose-6-phosphate dehydrogenases, have been identified. *Streptomyces lividans* harbors two *zwf* genes determining isozymes of glucose-6-phosphate dehydrogenases (the first enzyme in the oxidative pentose phosphate pathway [PPP]) and one gene (*devB*) encoding 6-phosphogluconolactonase (Butler et al., 2002). The fluxes through the pentose phosphate pathway and the tricarboxylic cycle relative to glucose uptake have been evaluated in *S. noursei* using C¹³ labeling experiments (Jonsbu et al., 2001). The final goal will be to analyze metabolic fluxes (Wehmeier, 2001; Bentley et al., 2002).

Glutamine synthetase I (GSI) in *S. coelicolor* A3(2) is posttranslationally controlled by adenylyltransferase (as in enteric bacteria), but the regulation of GSI differs (Hesketh et al., 2002). A new class of glutamate dehydrogenases (GDH) has been identified within *S. clavuligerus* (Minambres et al., 2000). During balanced growth either mineral or organic nitrogen sources are readily used by *S. pristinaespiralis*. Glutamate and alanine serve as both nitrogen and carbon sources, whereas valine is only used as a nitrogen source, which consequently leads to excretion of 2-ketoisovalerate.

Upon phosphate limitation, glycerol originating from the breakdown of teichoic acids is released, leading to the recovery of phosphate from the cell wall (Voelker and Altaba, 2001). The biosynthesis of most secondary metabolites is strongly depressed by inorganic phosphate. The two-component system, PhoR (phosphate regulon sensor protein) and PhoP (DNA-binding response regulator protein), was shown to control pathways for primary and secondary metabolites (Sola-Landa et al., 2003).

A novel pathway utilizing acetate as the sole carbon source has been discovered within *S. collinus* (Han and Reynolds, 1997). *Streptomyces coelicolor* A3(2) can use fatty acids (C4-C18) as the sole carbon source, and enzymes for their *in vivo* β -oxidation have been identified (Banchio and Gramajo, 1997). The glyoxylate cycle comprising isocitrate lyase and malate synthase is an anaplerotic pathway and essential for growth with acetate as the sole carbon source. Corresponding genes have been identified within *S. clavuligerus* (Soh et al., 2001). Malonate is a three-carbon dicarboxylic acid and it is well known as a competitive inhibitor of succinate dehydrogenase. The genes *matB* and *matC* have been successfully used in generating industrial strains of *Streptomyces* employed in the production of antibiotics (Kim, 2002).

It will be necessary to investigate the pathways and genes required for the biosynthesis of primary compounds, examine the regulation (Rodríguez-Garcá et al., 1997), and explore

metabolic fluxes (Obanye et al., 1996), as the precursors of pharmacologically active compounds are derived from primary metabolites. Proteins involved in primary and secondary metabolism are currently under investigation using proteomic analysis (Hesketh et al., 2002). Expression patterns of many genes involved in metabolic pathways can also be investigated by using microarrays (Huang et al., 2001). Recent data suggest that global changes in gene expression during stages of diauxic growth, adaptation or starvation can be analyzed by gathering proteomic and metabolomic data (Novotna et al., 2003). Recently, the basis for transcriptome analysis has been established (Bucca et al., 2003).

Pharmacologically Active Substances

Diversity of Compounds

Streptomycetes synthesize an amazing variety of chemically distinct substances, many of which act as antibiotics, fungicides, cytostatics, or modulators of immune responses, and a huge diversity of ever increasing numbers of inhibitors for many different cellular processes. New *Streptomyces* isolates provide sources of novel natural compounds.

Strategies for the Identification of Gene Clusters

Genes encoding these pharmacologically active substances are located within DNA stretches of 20 kb to more than 100 kb. Cloning had been achieved by complementing mutants, by screening total genomic DNA or gene libraries with homologous or heterologous gene probes generated by cloning or with the help of polymerase chain reactions (PCR), and by transposon mutagenesis. The biosynthetic genes for antibiotics are frequently located near one or more genes mediating resistance to the corresponding antibiotic. Accordingly, the initial identification of such resistance genes has often facilitated the identification of a biosynthetic cluster. Protein-patterns change drastically during the production of secondary metabolites. Proteins deduced to be involved in the synthesis of secondary metabolites can be analyzed by various biochemical methods as well as by mass spectroscopy. NH₂-terminal and internal amino acid sequences of characteristic proteins can be determined to design oligonucleotides useful for screening gene libraries and thereby identifying the desired gene cluster.

The gene-cluster for the synthesis of the polyketide actinorhodin (Malpartida and Hopwood, 1984) was achieved by comple-

mentation of mutants. Subsequently, many other gene clusters for polyketides were cloned using a gene-probe for the predicted key step for polyketide synthesis. These polyketides include: daunorubicin (Stutzman-Engwall and Hutchinson, 1989), frenolicin (Bibb et al., 1994), granaticin (Sherman et al., 1989), griseusin B (Yu et al., 1994), jadomycin B (Han et al., 1994), mithramycin (Lombo et al., 1996), tetracyclines (Binnie et al., 1989), tetracenomycin C (Motamedi and Hutchinson, 1987), tetrangomycin (Hong et al., 1997), and urdamycin A (Decker and Haag, 1995). The utilization of *pks* (polyketide synthase) genes as probes has made possible the identification of a continuously increasing number of biosynthetic gene clusters. Analysis by PCR has led to the discovery of many *pks* genes in various microorganisms, including hitherto nonculturable ones.

Genes for several clusters of macrolides were identified, including the genes for carbomycin (Epp et al., 1987), oleandomycin (Swan et al., 1994), rapamycin (Schwecke et al., 1995), and tylosin (Fishman et al., 1987). Furthermore, the genes for peptide antibiotics (such as actinomycin [Stindl and Keller, 1994; Hsieh and Jones, 1995] and biolaphos [Murakami et al., 1986]) and cyclopentenoid antibiotics (such as methylenomycin; Chater and Bruton, 1985) were identified. Additionally genes were discovered for synthesis of nikkomycin (a nucleoside-peptide; Bormann et al., 1996), nosiheptide (a thiopeptide; Dosch et al., 1988), undecylprodigiosin (a pyrrole; Feitelson and Hopwood, 1983; Malpartida et al., 1990), ansamycins (such as rubradirin [Sohng et al., 1997] and rifamycin [August et al., 1998]), aminoglycosides (such as puromycin [Lacalle et al., 1992] and streptomycin [Ohnuki et al., 1985; Distler et al., 1987]), carbapenems (Nakata et al., 1989), cephamycin (Aharonowitz and Cohen, 1992; Paradkar et al., 1996) and cyclopilins (Pahl et al., 1997).

Following the above-cited pioneering work, cloning of genes for many biosynthetic pathways has been extended enormously (see reviews by Champness [1999], Meurer and Hutchinson [1999], and Challis and Hopwood [2003]). In addition to conventional studies of transcription (Kelemen et al., 1994), novel approaches apply the application of DNA microarrays to instigate growth phase responsive expression of genes for antibiotic biosynthetic pathways (Huang et al., 2001).

Towards Engineering of Pathways

Polyketides constitute a diverse class of substances, including antibiotics, anticancer and antiparasitic pigments, and immunosuppressants (see also above). Because gene clusters for

polyketides are easy to detect, they are among the most studied. Consequently, a wealth of information has accumulated. The synthesis of polyketides requires polyketide synthases (PKSs) which are either multifunctional (type I; Cortes et al., 1990; Donadio et al., 1991; Weber et al., 2003) or monofunctional (type II; Bibb et al., 1989; Fernandez-Moreno et al., 1992). Type I PKSs are multifunctional enzymes consisting of modules, which control the sequential addition of acylthioester units to a growing polyketide chain and the subsequent modification of the condensation products. In contrast, Type II PKSs are composed of three to seven separate mono- or bifunctional proteins that are required repeatedly for the formation of the polyketide chain and some of its modifications. Both PKS types are biochemically similar to fatty acid synthases and catalyze decarboxylative condensations between a thioester-linked nascent carbon chain and short-chain fatty acid extender units. However, PKSs can use different starter molecules (acetate, propionate and butyrate) and chain extenders (malonate, methylmalonate and ethylmalonate) at various steps. Whereas condensations of fatty acids are typically followed by a trio of reactions (β -ketoreduction, dehydration and enoylreduction), a PKS may employ all, some or none of these reactions after each condensation step. Thus, the structural diversity of polyketides is due to the variable numbers and types of acyl units, reduction, dehydration, cyclization and aromatization reactions of the initial β -ketoacyl condensation products (Hopwood and Sherman, 1990; Donadio et al., 1991; Aparicio et al., 1994; Hutchinson and Fujii, 1995).

Multifunctional enzymes specify the choice of substrates and their sequence during a non-ribosomal process for synthesis of oligopeptide antibiotics. Each amino acid (which may also be a nonprotein type) may undergo C₂-epimerization, C- or N-methylation, halogenation, and various types of oxidation reactions during or after assembly of the carbon backbone. Oligopeptides can be linear or circular and may occasionally comprise attached acyl groups or sugars (Lawen and Zocher, 1990; Von Döhren and Kleinkauf, 1997; Zuber and Marahiel, 1997).

Having established the key steps, the principal rules for the synthesis of polyketides, peptide antibiotics, β -lactams, aminoglycosides and other classes have emerged. Thorough analysis of this accumulated information meanwhile allows the design of a broader diversity of biosynthetic pathways. The modular arrangement of biosynthetic gene clusters facilitates the construction of hybrid gene clusters. Consequently, a tailoring of antibiotics will complement the screening for new antibiotics and thereby help overcome the

problems linked to the broad repertoire of antibiotic resistances developed by pathogenic microorganisms.

Ecology

Habitats

Soil is the most important habitat of streptomycetes. Most soils contain 10^4 to 10^7 colony-forming units of streptomycetes per gram, representing 1–20% or even more of the total viable counts. Grass vegetation or soil rich in organic matter contain the highest numbers of streptomycetes. Most *Streptomyces* species prefer a neutral to mildly alkaline pH. However, several reports prove that some strains also grow under acidic (ca pH 3.5) or alkaliphilic (pH 8–11.5) conditions. As expected, streptomycetes settle in soil as microcolonies on particles of organic matter. In terrestrial habitats, streptomycetes constitute the most abundant actinomycete (90% or more). Mesophilic streptomycetes play an important part during the initial decomposition stages of organic material in compost (Kutzner, 1981). This process is achieved by the efficient enzyme-repertoire leading to the degradation of polysaccharides and other macromolecules (see above, the section Role of Secreted Proteins). Streptomycetes inhabiting aquatic and marine environments have also been investigated (Okami et al., 1976; Ravel et al., 1998). Thorough studies of lake sediments showed a dominance of *Micromonospora* species, whereas *Streptomyces* species were the secondmost abundant microorganisms (Jiang and Xu, 1996). Like strains from soils, aquatic streptomycetes produce compounds with antibacterial and antifungal activities (see the section Pharmacologically Active Substances in this Chapter) and have the capacity to hydrolyze a wide range of macromolecules including cellulose, chitin and proteins (see above). Furthermore, they have been suggested to play a major part in the turnover of toxic compounds.

Streptomycetes occur at higher concentrations in the gut of earthworms and arthropods. Some highly cellulolytic strains were isolated from the gut of termites (Kutzner, 1981; see the The Family Streptomycetaceae, Part I: Taxonomy in this Volume).

Actinomycetes, including various *Streptomyces* species, were identified within hydrocarbon-polluted soils and were found to utilize them as sole carbon sources. So far, the biochemical details have not been exploited. Streptomycetes were also found in soils contaminated with heavy metals. The molecular mechanisms of their resistances to heavy metals were until now barely

known. Recently, nickel-resistance was attributed to a transporter (Amoroso et al., 2000).

Some *Streptomyces* strains utilize a wide range of structurally diverse phosphonates as the sole phosphorus source and it is very likely they have a hitherto unique pathway for breakage of C-P bonds (Obojska and Lejczak, 2003). *Streptomyces thermoautotrophicus* is a thermophilic, CO- and H₂-oxidizing obligate chemolithoautotrophic organism (Gadkari et al., 1992) whose ability for N₂ fixation involves a molybdenum dinitrogenase and a manganese-superoxide oxidoreductase (Ribbe et al., 1997). A unique system leading to N₂ and nitrous oxide (N₂O) through denitrification and codenitrification has been discovered within *S. antibioticus* (Kumon et al., 2002).

Actinomycetes have been detected and localized by the dilution plate technique, either without enrichment or under special selective isolation conditions (for details, see The Family Streptomycetaceae, Part I: Taxonomy in this Volume). Recently however, hybridization techniques using fluorescent, genus-specific 16S rRNA probes have been developed for a broad range of bacteria (Roller et al., 1992). Such oligonucleotides can be used to detect uncultivable streptomycetes in situ. The increasing application of molecular tools should considerably deepen our knowledge of the ecological role of actinomycetes.

Interaction with Plants

The rhizosphere of plants comprises varying amounts of actinomycetes. Presumably, secretion of antibacterial and antifungal compounds plays an important role in natural habitats (Kutzner, 1981). Using molecular detection methods, streptomycin-producing *Streptomyces* strains have been found to colonize the rhizosphere of soybeans (Huddleston et al., 1997). Previous investigations suggested that some streptomycetes serve as potential biocontrol agents against fungi within the rhizosphere (Kutzner, 1981) and recent studies support this interpretation (Blaak and Schrempf, 1995; Yuan and Crawford, 1995; Kolbe et al., 1998).

Plant-pathogenic streptomycetes produce different types of potato scab (for review, see Kutzner, 1981). Studies of DNA-DNA hybridization and rRNA studies revealed that the pathogenic *Streptomyces* strains are phylogenetically diverse (see The Family Streptomycetaceae, Part I: Taxonomy in this Volume). The production of thaxtomins (a family of 4-nitroindol-3-yl-containing 2,5 dioxopiperazines) has been correlated with plant pathogenicity (King and Lawrence, 1996). Recent evidence shows that the peptide synthetase genes *txtAB* (*S. acidiscabies*)

are required for thaxtomin biosynthesis (Healy et al., 2000). The *nec1* gene encodes a putative virulence factor (Bukhalid and Loria, 1997). A gene encoding an extracellular esterase of an *S. scabies* strain was cloned and has so far only been identified in streptomycetes causing potato scab. Nonpathogenic, antibiotic-producing streptomycetes reduce potato scab in soil (Neeno-Eckwall et al., 2001). *Streptomyces ipomoeae* strains are sweet potato pathogens. The bacteriocin ipomicin has been found to lead to inter-strain inhibition (Zhang et al., 2003).

Yokonolide B, a spiroketal-macrolide, inhibits the expression of auxin-inducible genes in *Arabidopsis*. As this compound blocks auxin-dependent cell division and auxin-regulated epinastic growth mediated by auxin-binding protein 1, it provides a new tool to dissect auxin signal transduction (Hayashi et al., 2003).

Perspectives

The development and application of many molecular tools have considerably deepened our understanding of the biology of streptomycetes. We can expect that the currently available as well as future knowledge will enormously extend our ability to tailor hybrid antibiotics, cytostatics, antifungals, and antiparasitics, as well as other biologically active substances. The usage of current as well as new tools will lead to a much better understanding of the many processes within the environment that are due to streptomycete activities including humus formation, breakdown of many different macromolecules, modification of xenobiotics, and detoxification of harmful compounds. An exciting avenue is the elucidation of the molecular basis for interactions between streptomycetes and other microbes, plants and animals. To resolve this complexity, the ever-increasing knowledge about genomic processes, proteomes, transcriptomes, global networks, and signal transduction pathways will need to be integrated with studies of physiology, biochemistry and chemistry.

The Genus *Actinoplanes* and Related Genera

GERNOT VOBIS

Sporeforming actinomycetes related to the genus *Actinoplanes* are combined at present under the suprageneric group named “actinoplanetes” (Goodfellow, 1989). Originally, the term actinoplanetes was used ecologically to describe the strains of *Actinoplanes* and a small number of their relatives (Nonomura and Takagi, 1977). The members of the genus *Actinoplanes* all produce sporangia that release actively swimming spores. Later, the term actinoplanetes was expanded to encompass also the five genera *Amorphosporangium*, *Ampullariella*, *Pilimelia*, *Dactylosporangium*, and *Micromonospora*, which all have a common cell wall chemotype containing *meso*- and/or 3-hydroxy diaminopimelic acid and glycine in combination with xylose and arabinose as the characteristic sugars in the hydrolysates of whole organisms (Goodfellow and Cross, 1984).

The GC content of their DNA is in general 71–73 mol% (Vobis, 1989a), but recent studies have expanded the range to 67–76 mol% (Kothe, 1987). All genera of the actinoplanetes studied so far belong to one RNA homology cluster (Stackebrandt and Woese, 1981), excluding the sporangiate genera *Streptosporangium*, *Spirillospora*, *Planomonospora*, and *Planobispora*, which were classified for a long time within one family together with *Actinoplanes* (Bland and Couch, 1981). The genera excluded were placed temporarily into a suprageneric group called the “maduromycetes” (Goodfellow, 1989). According to Goodfellow et al. (1990) and Kothe (1987), the members of the actinoplanetes can now be harbored taxonomically in the newly defined family Micromonosporaceae, and those of the maduromycetes belong in the family Streptosporangiaceae (see this Volume).

The genus *Actinoplanes* was first described by Couch (1950), who called attention to its close similarities in colonial characteristics to the genus *Micromonospora* (Bakker, 1923), which produces single nonmotile spores. Our knowledge of the sporangiate members was extended by subsequent descriptions of further genera: *Ampullariella* and *Amorphosporangium* (Couch, 1963), *Pilimelia* (Kane, 1966), and *Dactylosporangium* (Thiemann et al., 1967). In recent years, two new genera have been added: *Glycomyces* (Labeda et al., 1985) and *Catellatospora* (Asano and Kawamoto, 1986). Both genera form nonmotile spores in chains. Although their chemotaxonomic features suggest convincing arguments for placing them into the actinoplanetes group, their phylogenetic relationships still need to be investigated (E. Stackebrandt, personal communication).

Ecophysiology

Without applying selective procedures, it is difficult to isolate the members of *Actinoplanes* and related genera from soil or other natural substrates. Although they are mesophilic and aerobic organisms, the growth rate of their colonies is often very slow, and on routine isolation plates, the fast-growing streptomycetes can overrun them before they have developed conspicuous mycelia. Furthermore, they exhibit quite varied types of reproductive structures, which are connected with distinct life cycles: 1) the genera *Actinoplanes*, *Ampullariella*, *Pilimelia*, and *Dactylosporangium* form sporangia with flagellated spores and are adapted to a periodic wetting and drying of the habitat; 2) the hydrophilic, nonmotile spores of *Micromonospora* are passively disseminated in water and in soil, again distributed by wind or rain; and 3) the genera *Catellatospora* and *Glycomyces* produce nonmotile, hydrophobic spores in chains, presumably associated with other survival strategies.

Sporangiate Actinoplanetes

The life cycles of the sporangiate genera are based on an alternation between terrestrial and “aquatic” habitats. The growth of vegetative mycelium on plant or animal residues culminates in the differentiation into sporangia, which are produced in general on the surface of the substrate, directly in contact with the air (Figs. 1F, 2C, 4A, and 7B) (Bland and Couch, 1981). The sporangia can easily lose their connection to the degenerating mycelium and are disseminated as diaspores by the wind or by soil fauna such as mites, collembola, or arthropods. The sporangia can withstand prolonged desiccation and survive for many years (Makkar and Cross, 1982). The sporangial envelope is usually water repellent. But if sporangia become rehydrated by sufficient moisture, e.g., during periods of fog or rain, the spores inside the sporangia begin to swell, the sporangial envelope bursts, and the flagellated spores are released. Under laboratory conditions, this process takes 10 to 60 min (Higgins,

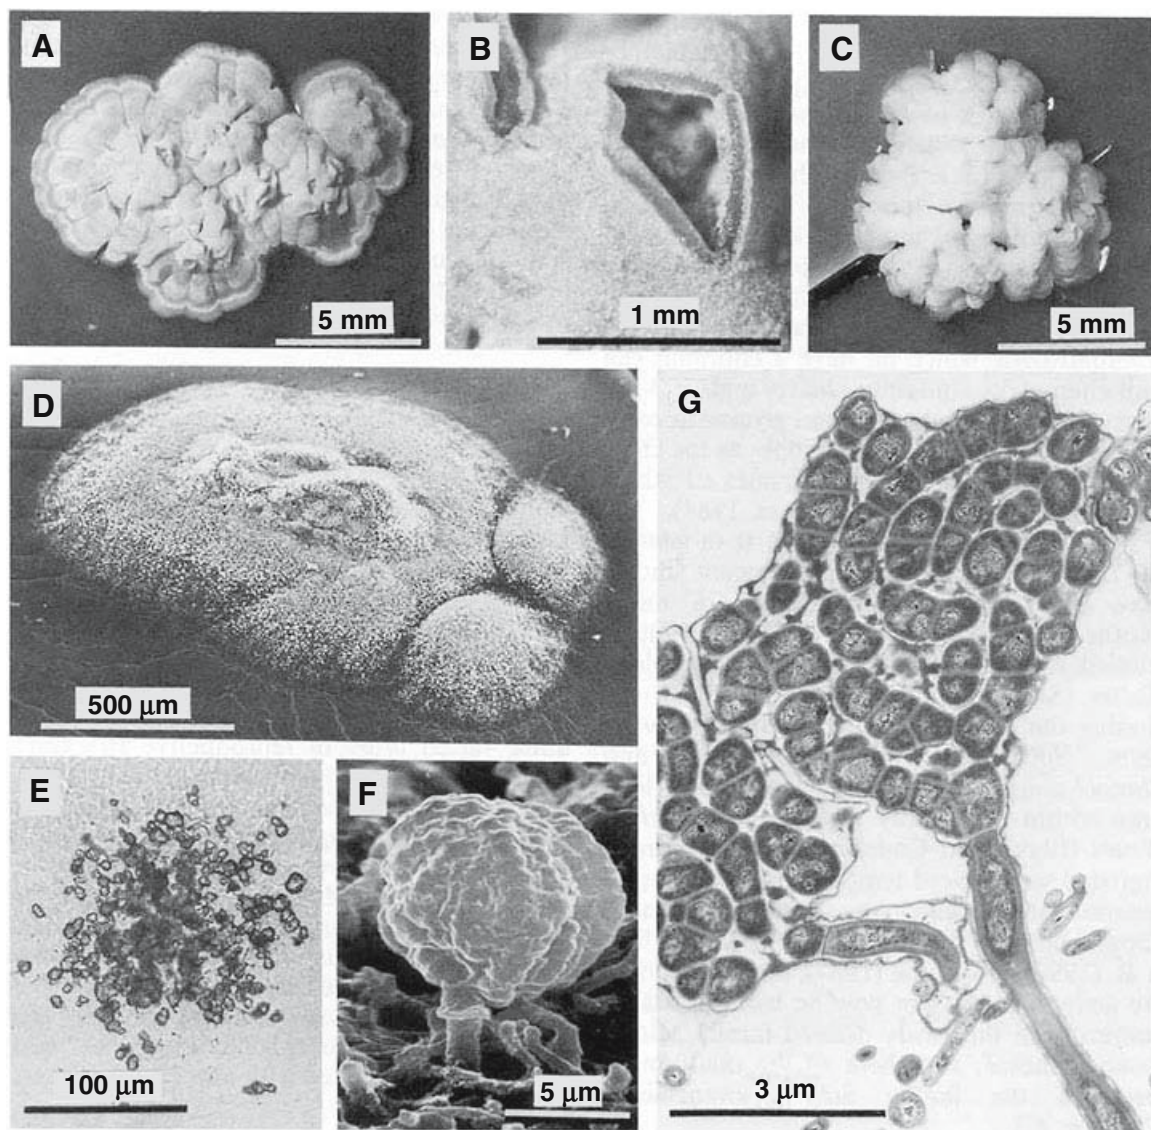

Fig. 1. Features of the genus *Actinoplanes*. (A) Colony with rough surface; marginal areas divided into radial and concentric sections, dissecting microscope (DM). (B) Burst substrate mycelium covered with a mass of sporangia (DM). (C) Elevated colony with squamules; smooth surface without sporangia (DM). (D) Flat colony with abundant sporangia visible on the substrate mycelium, scanning electron microscope (SEM). (E) Irregularly shaped sporangia on agar medium, light microscope (LM). (F) Globose sporangium at the tip of a palisade hypha (SEM). (G) Section of a sporangium with coiled chains of spores, transmission electron microscope (TEM). (G from Kothe, 1987; with permission.)

1967; Vobis, 1984, 1987). Spores of *Actinoplanes brasiliensis* retain their motility for more than one day in liquid mineral medium with glucose (Palleroni, 1983). Even without an exogenous source of energy, the zoospores of *Dactylosporangium* species are motile for two to three days before they germinate (Vobis, 1987). Reserve substances are included in their cytoplasm (Fig. 4C), possibly consisting of trehalose (J. C. Ensign, personal communication).

The zoospores of *Actinoplanes* exhibit chemotactic properties. In *A. brasiliensis*, Palleroni (1976) found bromide and chloride ions acting as

attractants at a relatively high concentration (0.1 M). Addition of methionine stimulated this chemotactic effect, suggesting that protein methylation may be involved (Palleroni, 1983). Not all species of *Actinoplanes* are attracted by halides. Spores of *A. missouriensis* were attracted to fungal conidia, chlamydospores, and sclerotia and to exudates of them (Arora, 1986). Several sugars had the same function. An extract of cattle horn meal can be more attractive to the spores than chloride ions are (G. Vobis, unpublished observations). Phototactic effects could not be observed, but an apparent microaerophilic

Fig. 2. Features of the genus *Ampullariella*. (A) Colony on agar medium, covered with a bloom-like layer of sporangia (SEM). (B) Sporangia on substrate mycelium, phase contrast (PHACO). (C) Campanulate sporangia; sporogenous hyphae are recognizable under the sporangial envelope (SEM). (D) Section of a cylindrical sporangium with parallel rows of bacilliform spores (TEM). (D from Vobis, 1987; with permission.)

behavior was seen in *A. brasiliensis* (Palleroni, 1976). In baiting experiments simulating an aquatic microhabitat, pollen or hair is exposed to the surface of water. The zoospores, once released from the submerged sporangia, are able to swim to the surface, fasten to the natural substrates, germinate, and colonize them within several days (Couch, 1963; Vobis, 1984). This may be a result of aerotactic and chemotactic behavior of the spores (Cross, 1986). Although the chemotactic response is used effectively in the isolation method of Palleroni (1980), the exact physiological explanation is not yet known.

The members of the genus *Dactylosporangium* have an additional variant in their life cycle. Beside the typical few-spored sporangia (Fig. 4A–C), they can develop “globose bodies” (Thiemann et al., 1967). These are spores that are borne singly on substrate hyphae (Fig. 4D–F).

Ensign (1978) demonstrated that these spores are able to germinate on 1.0% (w/v) yeast extract agar medium. The zoospores may function to insure a prompt dissemination in water, and the globose spores, which are constitutively dormant, may survive long periods of starvation or desiccation (Ensign, 1978). Likewise, treatment with dry heat (1 h at 120°C) seems to have no adverse effect on the dormant globose spores of *Dactylosporangium*, in contrast to the sporangiospores of other actinoplanetes (Shearer, 1987).

In general, the sporangiate actinoplanetes can be considered as normal inhabitants of the soil and leaf litter (Cross, 1981a), although they can also be isolated directly from lake or river water (Willoughby, 1969b, 1971). They colonize vegetable or animal debris preferably (Cross, 1981a). A frequent drying and wetting of the substrate

Fig. 3. Features of the genus *Catellatospora*. (All SEMs.) (A) A sporulating colony. (B) Sporeforming hyphae on the surface of agar medium. (C) Short spore chains emerging from substrate hyphae. (D) Branched spore chains on rudimentary sporophores containing cylindrical to ovoid spores.

increases their occurrence. Favored habitats are the edges of ponds, drainage ditches, and barnyards (Shearer, 1987). Sediments of rivers seem to be also a good source for the isolation of *Actinoplanes* species (Goodfellow et al., 1990). They can also be frequently isolated from twigs submerged in streams (Willoughby, 1971), muddy dead leaves that are caught and dried on branches of overhanging trees (Cross, 1981a), and from allochthonous leaf litter cast up on the shores of lakes (Willoughby, 1969a). Rarely, strains of *Dactylosporangium* can be encountered in lake sediments. Possibly survival depends on the globose spores (Johnston and Cross, 1976). Also, marine sediments are not very productive habitats for sporangiate actinoplanetes (Goodfellow and Haynes, 1984).

The genus *Actinoplanes* has a world-wide distribution (Couch, 1963; Gaertner, 1955; Vobis, 1987; Schäfer, 1973; Nonomura and Takagi, 1977). Strains of *Actinoplanes* occur in all types of soil, arid desert areas (Makkar and Cross, 1982), sand dune systems close to seashores (Palleroni, 1976), and subtropical and tropical regions. The most productive samples seem to originate from the latter (Shearer, 1987). In a

large-scale investigation of the distribution of actinoplanetes in soil in Japan, Nonomura and Takagi (1977) demonstrated a correlation among their abundance, the type of soil, its pH value, and the content of organic matter. Relatively few actinoplanetes occurred in soils with pH 4.0 to 5.0 and abundant organic matter content. Their number increased with lower humus content and a pH value between 6.4 to 7.2. Soils with a permanent high content of water (e.g., paddy rice fields) have no advantage compared with cultivated fields, which are dry for longer periods.

Strains of *Ampullariella* are widely distributed throughout the world (Couch, 1963). A little less than 10% of the isolated sporangiate actinoplanetes are represented by this genus (Schäfer, 1973; Vobis, 1987). *Ampullariella* could also be obtained from freshwater habitats (Willoughby, 1969b).

The function of sporangiate actinoplanetes in soil ecosystems is not really known. With the exception of a few strains, the *Actinoplanes* species cannot decompose cellulose (Parenti and Coronelli, 1979; Palleroni, 1989). Although they can be isolated on colloidal chitin agar medium,

(C, D, and F from Vobis, 1987; with permission.)

degradation tests with chitin from insects and fungi gave negative results (Schäfer, 1973). Since they exhibit good growth on xylose and arabinose, it is conceivable that they play a role in decomposing pentosans of plant origin (Parenti and Coronelli, 1979). *Pilimelia* strains are able to colonize keratinic substrates like hair of mammalia or snake skin (Karling, 1954; Gaertner, 1955; Tribe and Abu El-Souod, 1979). They are distributed worldwide and occur statistically in about one of every five soil samples (Schäfer, 1973; Vobis et al., 1986). Although they can aggressively attack the scleroproteins of animals (Fig. 7C), they are not known as dermatophytes.

MICROMONOSPORA Members of the genus *Micromonospora* can be commonly isolated from neutral and alkaline soils (Jensen, 1930; 1932) and according to Shearer (1987), two or three strains may be expected from most soil

samples. However their predominant incidence seems to be in aquatic ecosystems, including both freshwater and marine habitats (Cross, 1981a; Goodfellow and Haynes, 1984). Since they decompose chitin, cellulose, and lignin of lake sediments they might play an important role in lacustrine ecology (Erikson, 1941). The presence of *Micromonospora* in lake systems has been shown by investigations in many countries and was comprehensively reviewed by Cross (1981a, 1981b). Beside streptomycetes and nocardioforms, the micromonosporas were the predominant actinomycetes in the bottom sediments of Blelham Tarn UK, with numbers increasing from littoral to profundal mud samples (Willoughby, 1969b). This dominance was even more striking in deeper mud layers, as could be shown in studies of other lakes of the English Lake District (Johnston and Cross, 1976). Similar observations were made by Fernandez (1984) at a thermal

lake, Lake Hévíz, in Hungary. Compared with the surface of the mud, the number of micromonosporas increases twofold in 20 cm of depth, whereas the number of streptomycetes decreases significantly in the same layer. Under those conditions, the spores of *Micromonospora* seem to be more resistant than the propagules of *Streptomyces* and nocardioform actinomycetes. This could be confirmed in investigations on the longevity of actinomycete spores in deep mud cores. Viable spores of *Micromonospora* were recorded from sediments deposited at least 100 years before (Cross and Attwell, 1974). Populations of *Micromonospora* species, accompanied by other actinomycetes, have also been frequently found in streams and rivers (Rowbotham and Cross, 1977; Al-Diwany and Cross, 1978). Their spores are hydrophilic and wettable (Fig. 6C) and can easily be removed from soil by the passage of water (Ruddick and Williams, 1972). The spores withstand ultrasonication, moist heat treatment (20 min at 60°C), and dry heat up to 75°C, and they are resistant to various chemical solutions. However, they are somewhat sensitive to acidic pH (Kawamoto, 1989). Thus, the conclusion can be drawn that the spores of *Micromonospora* are washed into the streams,

rivers, and lakes where they can survive as dormant propagules for many years (Cross, 1981a).

Micromonospora species have been isolated from many different marine habitats, ranging from coastal regions to deep-sea sediments. Hunter et al. (1981) found abundant micromonosporas in salt marsh ecosystems in New Jersey (USA), with seasonal fluctuations in quantity. In a study at the San Francisco Bay (USA) National Wildlife Refuge, Hunter et al. (1984) showed that micromonosporas occur more frequently in rhizospheric soils of seashore plants than in mud samples obtained from plant-free areas. Watson and Williams (1974) studied the actinomycetes in a coastal sand belt near Formby, Lancashire (UK). In sea water and beach strand, the *Micromonospora* strains predominated. They grew well on freshwater media and most of them tolerated seawater salinity. Okazaki and Okami (1972) and Okami and Okazaki (1978) isolated micromonosporas from littoral muds and from samples collected in shallow sea areas of the Pacific Ocean, occurring more frequently at the bottom than in the sea water. Weyland (1969, 1981) found that the micromonosporas predominated in the deep-sea sediments, and his results were confirmed by

Goodfellow and Haynes (1984). The ability of *Micromonospora* strains to tolerate reduced oxygen tensions (Watson and Williams, 1974) favored the view that after the spores sink into the sea, they settle into littoral or marine sediments where they can survive for long periods of time (Goodfellow and Williams, 1983). Other authors suggest that the actinomycetes are a part of the indigenous marine microflora, able to grow in seawater and its sediments (Okami and Okazaki, 1978; Weyland, 1981).

The presence of *Micromonospora* species could also be established in terrestrial habitats like straw and hay, in grain stores, or as pollutants of the aerial environment in homes. They also can be found in structural timbers, chiefly those found below the watertable in the foundation piles of buildings. They have also been found in the trunks of trees of the genera *Picea* and *Pinus* and in pulp from paper mills (Lacey, 1988).

Most *Micromonospora* species probably degrade biopolymers (Erikson, 1941), and they can even attack lignin complexes (McCarthy and Broda, 1984). Many of the salt marsh isolates of Hunter et al. (1981) were active in the decompo-

sition of chitin and cellulose. In particular, cellulose is frequently utilized as substrate (Jensen, 1930; Sandrak, 1977; Kawamoto, 1989). The cellulase studied from *Micromonospora melanospora* was found to be more heat stable than those of the imperfect fungus *Trichoderma*, but less stable than the enzymes of thermophilic actinomycetes. The principle sugar released by *Micromonospora* cellulase from ball-milled bagasse and filter paper was cellobiose (Van Zyl, 1985).

It is possible that micromonosporas are able to grow under microaerophilic conditions, as would be found in wet soils (Goodfellow and Williams, 1983). However, the strictly anaerobic *Micromonospora* strains isolated from the intestinal tract of termites (Hungate, 1946) and from the rumen of sheep (Maluszyńska and Janota-Bassalik, 1974) urgently require taxonomical studies to clarify their affiliation to the genus *Micromonospora*.

CATELLATOSPORA AND *GLYCOMYCES* As Asano et al. (1989b) emphasized, all their isolates of *Catellatospora* species were recovered from woodland soils collected at various localities from the

northern to the western part of Japan; no strains could be obtained from soils of agricultural fields or from sediments of lakes and rivers. The authors suggest that members of this genus are probably distributed widely in woodlands of temperate regions. *Catellatospora* has been isolated from a soil sample that originated from the pampas grassland south of Buenos Aires, Argentina (Vobis, 1987). Earlier descriptions of non-motile strains related to "*Dactylosporangium*" (Lechevalier and Lechevalier, 1970a; Thiemann, 1970) and the recent report of Meyerton et al. (1987) suggest a global distribution of these rare organisms.

The role of the singly produced globose spores, which can occur in addition to the non-motile spores in chains (Asano et al., 1989b), has not been studied yet, but they may have interest-

ing ecophysiological aspects similar to those of the *Dactylosporangium* spores.

It is premature to give ecological data for *Glycomyces* species. The two type strains were isolated from soil samples from Harbin, China, and from a greenhouse in Trenton, New Jersey, USA, respectively (Labeda et al., 1985).

Isolation

In agreement with the wide distribution of actinoplanetes in nature, samples from various habitats have proved to be favorable sources of inoculum: soil, sediment, mud, water, and plant material. Microbial populations vary greatly, so that only about one in four samples may prove successful (Shearer, 1987). Special pretreatments

of the freshly collected samples enhance the numbers of actinoplanetes and reduce the non-desirable concomitant microorganisms. Selective isolation media (see "Media for Isolation and Cultivation") favor their development and limit the growth of other bacteria and common soil actinomycetes like *Streptomyces* species. The addition of humic acid, for example, activates the germination of spores (Hayakawa and Nonomura, 1987), and media with low nutrient concentration favors the growth of *Micromonospora* (Rowbotham and Cross, 1977).

To avoid the growth of fungi on the isolation plates, cycloheximide (50 µg/ml) and/or nystatin (100 units/ml) can be added to the isolation medium (Shearer, 1987). The selective effect can be enhanced by the addition of other antibiotics like novobiocin, streptomycin, gentamicin, or tunicamycin, supplemented either solely or in combination (Table 1). *Actinoplanes*, *Ampullariella*, and *Micromonospora* strains could be isolated very selectively using the agar plate method with additions of cycloheximide, nystatin, or novobiocin (Torikata et al., 1978, 1983). A combination of tunicamycin and nalidixic acid permitted a selective growth of *Micromonospora* species (Nonomura and Hayakawa, 1988). Instead of antibiotic supplements, a special membrane filter technique can be used, since the branching hyphae of the actinoplanetes can penetrate the small filter pores, whereas bacterial growth is restricted to one side of the membrane (Hirsch and Christensen, 1983).

The differing behavior of the spores permits the use of two isolation methods: 1) direct isolation on selective agar media for the actinoplanetes having nonmotile spores and 2) techniques using spore motility to specifically enrich the sporangiate members. Obviously, strains belonging to one group can appear also on the isolation plates intended for the others.

The isolation plates and the enrichment cultures are usually incubated at 22 to 28°C. Because of the very slow growth rate of the actinoplanetes, the incubation time has to be extended up to several weeks in some cases. The use of a dissecting microscope is recommended to select the colonies grown on the isolation plates. The mycelia can be picked up and transferred with toothpicks or with a thin metal needle.

Isolation from Water

The freshly collected water samples should be stored at 4°C until processed. If necessary, the spores can be concentrated from a relatively large volume of water either by the membrane filtration technique described by Burman et al. (1969) or by centrifugation (Okami and Okazaki, 1972). To reduce the numbers of the

concomitant vegetative bacterial cells, a pretreatment either with 1) mild heating or 2) chemical substances is recommended.

1) For the heat treatment procedure, 2 ml of the water sample is placed in a glass tube which is sealed and heated in a water bath. Various periods of incubation and temperatures have been used: 6 min at 55°C (Rowbotham and Cross, 1977), 10 min at 70°C (Cross, 1981b), or 60 min at 44°C (Burman et al., 1969).

2) An alternative pretreatment with chlorine was suggested by Burman et al. (1969) and Willoughby (1969b): the samples are first treated with 4 mg/l ammonia, followed by 2 mg/l chlorine (added as 1 ml of a hypochlorite solution containing 200 mg/l of available chlorine). Samples are allowed to stand for 10 to 30 min; then the chlorine is neutralized with sodium thiosulfate. The correct amount has to be calculated from titration of a blank sample.

After brief mixing of the pretreated samples (either heat or chlorine), spreading can be carried out immediately with 0.2 ml of the sample on each agar plate (Rowbotham and Cross, 1977). If necessary, dilutions can be made, either with sterile buffer (0.5 M KH_2PO_4 adjusted with NaOH to pH 7.2; Hsu and Lockwood, 1975) or with quarter-strength Ringer's solution containing gelatin (0.01% w/v; pH 7.0; Rowbotham and Cross, 1977). The inoculated plates are incubated at 28 or 30°C for 3 to 4 weeks.

As shown in Table 1, using selective media, *Micromonospora* strains are mainly obtained on the isolation plates from water sources. *Actinoplanes* may also be isolated from water samples (Willoughby, 1971; Torikata et al., 1978).

Isolation from Soil and Sediments from Freshwater and Marine Habitats

SOIL-DILUTION-PLATE TECHNIQUES Soil samples, marine sediments, or mud from lakes and rivers are air-dried at room temperature and then ground in a mortar (Shearer, 1987). About 1 g of the sample is added to 10 ml of saline in a 25-mm test tube. The suspension is mixed (vortex mixer) for 1 min and diluted in series with a sterile salt solution. The salt solution proposed by Wakisaka et al. (1982) contains 0.01% $\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$ and 0.002% Tween, from which air is eliminated by use of a vacuum desiccator for about 30 min. Instead of a salt solution, sterile water can also be used for suspension and serial dilutions (Hayakawa and Nonomura, 1987). Petridishes are prepared one day before plating and incubated at 37°C overnight to eliminate films of moisture on the agar surface (Shearer, 1987). An 0.1-ml inoculum of the proper dilution is placed on each

plate and spread with a sterile glass rod. Plates are incubated at 28 to 30°C for 4 to 5 weeks.

Cellulose-decomposing micromonosporas can be isolated from soil adjacent to the roots of wheat and maize according to the method of Sandrak (1977). One ml of soil suspension is mixed with 0.67 g sterile cellulose powder (as used for thin-layer chromatography) and 2 ml of liquid Kadota's benzoate medium (Sandrak, 1977). The mixture is spread on plates with Kadota's benzoate agar. The cellulose layer is allowed to dry before the plates are incubated for 25–30 days at 28°C (Cross, 1981b).

For *Micromonospora* species from marine sediments, Goodfellow and Haynes (1984) incubated the isolation plates at 18°C for 10 weeks (duplicates at 4°C for 6 months).

Heat or chlorine treatment, as described for water samples, can also be used with soil and sediment dilutions (Cross, 1981b). An alkaline pretreatment method is suggested by Wakisaka et al. (1982): One ml of the diluent is mixed with 9 ml of 0.01 N NaOH. After standing for 5 to 10 min, the mixture is neutralized with 0.1 N HCl to pH 6 to 7 (with cooling) before serial dilution and plating. Nonomura and Hayakawa (1988) treated the soil-water suspension with 1.5% phenol at 30°C for 30 min.

The routine plating technique is preferable for the isolation of strains of the genera *Micromonospora*, *Dactylosporangium*, *Catellatospora*, and *Glycomyces*. Table 1 lists the results of the use of various selective agar media in combination with the additions of antibiotic agents.

DRY HEAT TECHNIQUE A procedure which involved dry heating of soil samples at extreme temperatures was originally developed by Nonomura and Ohara (1969) for the isolation of *Microbispora* and *Streptosporangium* species. Shearer (1987) demonstrated that this technique is also useful for the isolation of *Dactylosporangium* and *Micromonospora* strains (Table 1). The samples are first air-dried at room temperature and ground in a mortar. Then they are heated in a drying oven at 120°C for 60 min. One g of the heat-treated soil is added to 10 ml of saline solution and then processed as described for the routine dilution-plating technique. Inoculated plates are incubated at 28°C for 4 to 5 weeks. Arginine-vitamin agar and starch-casein-nitrate agar with B vitamins are used as selective media (Shearer, 1987).

STAMPING TECHNIQUE The stamp technique was used successfully in the study of actinomycete populations of salt marsh ecosystems (Hunter et al., 1984). Depending on the moisture content, the samples of soil or mud are air-dried in petri dishes for several days at room temperature. Two

methods of further pretreatment were suggested by Hunter-Cevera et al. (1986): 1) the dried samples are ground with a pestle in a mortar and heated for 2 hours at 60 to 65°C, and 2) dried samples are mixed with powdered chitin (1 : 1) and incubated for 2 to 3 weeks at 26°C.

The pretreated and ground samples are stamped onto the isolation plates using the following procedure: A small circular sponge (Dispo culture plug, 16 mm; Scientific Products) is pressed into the powdered sample and removed. The excess small crumbs are shaken off. A stack of a dozen plates with various different alternating selective media is then inoculated by successively "stamping" (lightly touching) the sponge to the agar surface 10 times in a circle around the perimeter and 3 times in the middle of each plate (Hunter et al., 1984). Continuously stamping with the same plug yields the desired dilution effect. Plates are incubated at 26–28°C for 2 weeks. Hunter-Cevera et al. (1986) recommend arginine-glycerol salts agar, starch-casein-nitrate agar, and thin pabulum agar as the selective media for the isolation of *Micromonospora* strains (Table 1).

Isolation from Plant Material

A special wash technique was employed by Willoughby (1968, 1969a) for the investigation of actinomycetes populations on decomposing leaf litter. The leaves are collected at a fairly early stage of the decomposition. Small pieces of approximately 3 cm² are cut out, and each piece is transferred to a 100-ml conical flask containing 25 ml of sterile-filtered lake water. After 2 min of agitation on a rotary shaker, small aliquots of the leaf washing liquid are either incorporated into molten agar (0.5 ml/plate) or spread onto the surface of agar, 0.2 ml for each plate, using a right-angled glass rod. The plates are incubated at 25°C for 3 to 5 weeks (Willoughby, 1968). The most successful isolation medium for strains of *Actinoplanes*, *Ampullariella*, and *Micromonospora* was colloidal chitin agar with cycloheximide as the antifungal agent (Table 1).

Special Isolation Methods Using Motile Spores

The following very selective isolation methods are used when dormant sporangia are present in the substrate to be tested. The sporangia can release actively swimming spores when submerged in water. The individual spores must be motile for many hours and must show positive chemotaxis to specific chemical substances. Once fastened to a natural or cultural substrate, they must be able to germinate and form new mycelia

Table 1. Examples of the direct isolation of actinoplanetes using selective media.

Source	Isolation method	Isolation medium	Agent added	Genus selected	Reference
Water	Dilution plate	Water agar or colloidal chitin agar	Potassium tellurite (0.1 % w/v)	<i>Actinoplanes</i>	Willoughby (1971)

Actinoplanes, Ampullariella, and Micromonospora					

ND, no data.

and, for use of the baiting technique, produce a new generation of sporangia.

BAITING TECHNIQUE The baiting technique is the classical isolation method for *Actinoplanes*, which made possible the first discovery of actinomycetes with motile spores (Couch, 1949). Although other powerful techniques are available, baiting is still the only way to isolate keratinophilic *Pilimelia* strains.

0.5 to 1.0 g of the sample is placed in a small, sterilized petri dish (3 or 4 cm in diameter) or in a chamber of a multi-well microtiter plate, which is then half flooded with sterile demineralized water. After cautiously stirring, the particles settle to the bottom. Natural baits are exposed singly or in combination on the surface of the water: pollen of *Pinus*, *Liquidambar*, or *Sparganium*, boiled *Paspalum* grass leaves, hair of mammalia (human, dog, deer, cattle, white mice, etc.), or bits of snake skin (Couch, 1949, 1954; Karling, 1954; Gaertner, 1955; Kane, 1966; Schäfer, 1973; Tribe and Abu El-Souod, 1979; Makkar and Cross, 1982). The baits must be presterilized, depending on their consistency, either chemically with ethanol or propylene dioxide or by autoclaving (Gaertner, 1955; Schäfer, 1973; Makkar and Cross, 1982). The baiting enrichment cultures are closed and stored undisturbed at room temperature for several weeks. The water level can be regulated by additions of sterile distilled water. The examination for actinoplanetes can begin after one week with a dissecting microscope using 100 \times magnification and horizontal lighting (Bland and Couch, 1981). Further examination after 3 to 4 weeks is recommended for keratinophilic organisms (Schäfer, 1973).

Sporangia of actinoplanetes are recognizable as glistening beads on the air-exposed sides of the baits. Such baits are then removed carefully from the water and transferred to a 3% agar plate (Bland and Couch, 1981). Individual sporangia are separated from the bait and rolled several centimeters over the surface of agar, using a thin-pointed tungsten needle, which has a tip curved like a hockey stick. In this way, contaminants are removed from the sporangial surface. Cleaned sporangia can be transferred either directly or together with a small, cut-out agar block onto a petri dish with suitable agar medium. Media for isolation from pollen and grass leaves include Czapek sucrose agar, peptone-Czapek agar (Bland and Couch, 1981), half-concentrated casamino acids-peptone Czapek agar (Schäfer, 1973), or Emerson's yeast extract-starch agar. Sporangia from keratinic baits should be transferred to highly diluted skim milk-cattle horn-meal agar (Vobis, 1984).

The colonies originating from the individual sporangia are visible with the naked eye after 1

to 4 weeks of incubation and can partly be used as the inoculum for the new strain on slant cultures. The other part of the mycelium can be transferred onto sporulation agar for morphological identification.

DEHYDRATION-REHYDRATION TECHNIQUE This technique utilizes the ability of the sporangia to withstand desiccation and to release motile spores when they are subsequently in contact with water. Besides soil samples, it is also applicable to leaf litter, decaying plant material from aquatic habitats, organic debris, etc. (Makkar and Cross, 1982).

The samples are dried at 28 to 30°C for 7 days. For rehydration, 0.5 g of soil or corresponding substrate is mixed with 50 ml of sterile tap water in a 150-ml beaker or Erlenmeyer flask, which is covered with sterile aluminium foil (Shearer, 1987; Vettermann and Prauser, 1979). The suspension is incubated at 20 to 30°C for about 1 hour. During the first 30 minutes, the vessel can be shaken at irregular intervals. After that, the particles should be permitted to settle. From the supernatant, 0.5 to 1.0 ml are removed with a sterile Pasteur pipette and spread onto agar plates (Shearer, 1987). If it is necessary, dilutions can be prepared from the inoculation fluid (Makkar and Cross, 1982). For cultivation, the following media can be used: soil extract agar; colloidal chitin agar containing cycloheximide and nystatin (Makkar and Cross, 1982); oatmeal-soil extract agar; and starch-casein-sulfate agar (Shearer, 1987). Plates are incubated at 28°C for 2 to 4 weeks. Colonies of actinoplanetes can be selected under a dissecting microscope at 60 \times magnification and used as inoculum for new strains.

CHEMOTACTIC METHOD The spores of *Actinoplanes* exhibit an apparently microaerophilic reaction and are attracted to chloride and bromide ions (Palleroni, 1976). Therefore, a chemotactic method can be used to isolate these strains. An essential part of this technique is a simple isolation chamber, a sterilizable plastic block (80 \times 40 \times 12 mm) with two circular holes (9 mm deep and 24 mm in diameter) whose centers are 32 mm apart. They are connected by a channel that is 2 mm wide and 3 mm deep (Palleroni, 1980). One gram of a soil sample is divided into two equal parts and then placed in each compartment. Sterile water is added nearly to the rim and stirred cautiously. After incubation for 1 hour at 30°C, the spores are released from the sporangia and move freely in the water. Using a sterilized tweezer, a sterile 1- μ l glass capillary about 32-mm long is filled with 0.01 M phosphate buffer (pH 7.0) containing 0.01 M KCl and placed in the channel. The capillary

must be submerged, connecting the two suspensions. After incubation at 30°C for 1 hour more, the attracted spores are concentrated in the lumen of the capillary, which is then removed and washed from the outside with a jet of sterile water. The contents of the capillary are blown into 1-ml sterile water or buffer. Portions of the dilution are taken with a sterile pipette and spread onto carefully dried agar plates. The plates are then incubated at 28°C. Starch-casein-sulfate agar is recommended as the isolation medium (Palleroni, 1980). Although colonies can be selected after 4 days, slowly growing actinomycetes may only be detectable after 3 weeks.

MOIST INCUBATION TECHNIQUE This method is suitable for the direct detection of actinoplanetes on natural substrate. Although the ability to produce motile spores obviously plays no role, *Actinoplanes* strains can be readily enriched (Willoughby, 1968). Portions of decaying leaves or other biological substrates, freshly collected from the field, are washed with sterile water to remove adhering detritus. They are placed in prepared petri dishes, the bottoms of which have been covered with very moist filter paper or layers of cellulose before autoclaving. The petri dishes, working as moist chambers, are sealed and incubated for about 4 weeks at 25°C. Examination with both dissecting and light microscopes is necessary to identify the sporangia of the actinoplanetes (Willoughby, 1969a).

Identification

As outlined by Labeda (1987) and Lechevalier (1989), a combined use of morphological and chemical criteria is still the best way to identify actinomycetes at the genus level. To start with simple and time-saving morphological studies can sometimes shorten large-scale chemotaxo-

nomical procedures. However, to verify the determination, biochemical analyses are still absolutely necessary.

Morphological Criteria

Because members of the actinoplanetes are highly differentiated morphologically, (Bland and Couch, 1981; Luedemann and Casmer, 1973; Vobis and Kothe, 1985), it is possible to use morphological criteria alone for identification at the genus level. Table 2 is a dichotomous key that can be used to determine the genus of the isolate being studied.

For morphological studies in general, the short guidelines compiled by Cross (1989) are useful. Tiny pieces of the mycelium from vigorously developing colonies are transferred to freshly prepared sporulation medium in small petri dishes. The temperature of incubation should be between 20 and 30°C, and observations are made after 2 days to 4 weeks of incubation (depending on the individual strain). Preliminary observations should be made with a dissecting microscope (Figs. 1A, B, and C; 6A, B, and C) and directly with a light microscope (Figs. 1E; 4A; 7B) before water mounts are prepared. The best magnification of undisturbed colonies is with 20 or 40× objectives so that appropriate structures can be accurately studied (Okami and Suzuki, 1958; Cross, 1981b). Spore chains and single spores can be detached by slight pressure on the colony with a cover slip. Sporangia should be cut out and mounted with water. Although observation with a bright-field microscope is generally sufficient, phase-contrast is often also helpful (Figs. 2B; 4D; 7D).

For observing spore release from the sporangia, water-mounted preparations should be observed continuously for 1 to 2 h; unchlorinated tap water or distilled water should be used. To avoid evaporation, slides should be stored in

Table 2. Determinative key for the actinoplanetes genera using morphological criteria.

1a Spores in chains	2
1b Spores not in chains	3
2a Spore chains long, on aerial hyphae	<i>Glycomyces</i>
2b Spore chains short, emerging from substrate hyphae	<i>Catellatospora</i>
3a Spores spherical, single on substrate hyphae, nonmotile	4
3b Spores enclosed in sporangia, motile by flagella	5
4a Diameter of spores: 0.7–1.5 µm, in clusters	<i>Micromonospora</i>
4b Diameter of spores: 1.7–2.8 µm, dispersed	<i>Dactylosporangium</i>
4c Diameter of spores: 0.4–0.6 µm, dispersed	<i>Catellatospora</i>
5a Sporangia oligosporous, with one row of spores	<i>Dactylosporangium</i>
5b Sporangia polysporous, with several rows of spores	6
6a Sporangiospores globose to subglobose	<i>Actinoplanes</i>
6b Sporangiospores bacilliform	7
7a Spores distinct rod-shaped, 2.0–4.0 µm long, tuft of flagella polar	<i>Ampullariella</i>
7b Spores rod-shaped to reniform, 0.7–1.5 µm long, tuft of flagella lateral	<i>Pilimelia</i>

Fig. 8. Morphology of the motile sporangiospores of the genera of the actinoplanetes. *Actinoplanes*: globose, ellipsoidal, short bacilliform (0.8–2.0 μm), with a polar tuft of flagella. *Ampullariella*: bacilliform (0.5–1.0 \times 2.0–4.0 μm), with a polar tuft of flagella. *Pilimelia*: bacilliform, reniform (0.3–0.7 \times 0.7–1.5 μm), with a lateral tuft of flagella. *Dactylosporangium*: cylindrical, ovoid or pyriform (0.4–1.3 \times 0.5–1.8 μm), with a polar or subpolar tuft of flagella. (From Vobis, 1987; with permission.)

moist chambers. Actively swimming spores are easy to distinguish from Brownian molecular movement since the action of the flagellar tuft causes the spores to move and rotate rapidly. Based on the type of flagellation, the spores of *Ampullariella* rotate around the longitudinal axis, while those of *Pilimelia* rotate around the lateral axis (Fig. 8). To observe the flagella with the light microscope, staining methods must be used (Couch, 1950), but the exact location of flagellar insertion can only be determined by transmission electron microscopy.

Although many strains sporulate readily on isolation media or on rich media used for subculturing, special agar media have to be used to obtain good sporulation of certain strains: Czapek sucrose agar for *Glycomyces harbinensis* (Labeda et al., 1985), *Dactylosporangium vinaceum* (Shomura et al., 1983), and *Ampullariella* spp. (Nonomura et al., 1979); calcium malate agar for *Dactylosporangium* spp. (Thiemann et al., 1967), *Actinoplanes* spp. (Palleroni, 1989), and *Catellatospora* spp. (Asano and Kawamoto, 1986); inorganic salts-starch agar for *Dactylosporangium* spp. (Vobis, 1989c) and *Ampullariella* spp. (Nonomura et al., 1979); humic acid-vitamin agar for *Dactylosporangium* spp. and *Micromonospora* spp. (Hayakawa and Nonomura, 1987); humic acid-ion agar for *Actinoplanes* and *Ampullariella* spp. (Willoughby et al., 1968); soil extract agar for *Dactylosporangium* spp. (Thiemann et al., 1967) and *Actinoplanes* spp. (Parenti et al., 1975); diluted skim milk-hornmeal agar for *Pilimelia* spp. (Vobis, 1984); oatmeal agar for *Actinoplanes* spp. (Bland and Couch, 1981); and M3 agar, supplemented with 0.1% (w/v) fructose (Goodfellow et al., 1990). An excellent routine sporulation agar is artificial soil agar (Henssen and Schafer, 1971). The compositions of two of the above, inorganic salts-starch agar and oatmeal agar, are described by Shirling and Gottlieb (1966). The formulations of some of the other media are given below. For morphological stud-

ies, the same natural substrate can be used as that used for the isolation by baiting or moist incubation (Fig. 7B and C).

Individual strains of *Actinoplanes*, *Ampullariella*, and *Pilimelia* may produce incomplete sporangiate structures. The sporogenous hyphae are still developed at the tip of the supporting hypha, but the sporangial envelope appears to be absent. Sometimes, the division into spores is not complete, so that the hyphae look like brushes or little trees. If the sporogenous hyphae are fragmented, the resulting spores are always arranged in chains (Fig. 7E). It is remarkable that these free, developed spores never have flagella. Therefore, they have been called "conidia" and the supporting hyphae "conidiophores" (Couch, 1954, 1963; Kane, 1966; Willoughby, 1966).

Isolates of the *Actinoplanes* group exhibiting marked morphological characteristics can be identified to the genus level with aid of the simplified determinative key given in Table 2.

Chemotaxonomical Criteria

The taxonomy of the actinoplanetes can be established 1) by the composition of the amino acids of the cell walls; 2) by the sugar pattern of whole cell hydrolysates; and 3) by the absence of mycolic acids. Further chemotaxonomical markers, such as the composition of: 4) the phospholipids; 5) menaquinones; and 6) fatty acids, also have, in many cases, an important diagnostic value. Table 3 lists the most useful chemotaxonomical properties of the actinoplanetes. The chemical features are not only good indicators for identification, but they are also very important with regard to suprageneric groupings and phylogenetical relationships (Goodfellow and Cross, 1984; Stackebrandt and Schleifer, 1984).

CELL WALL CHEMOTYPE According to the classification scheme of Lechevalier and Lechevalier (1970b), the members of the *Actinoplanes* group

Table 3. Chemotaxonomical characters of the genus *Actinoplanes* and related genera.^a

Genus	Cell wall chemotype ^b	Whole cell sugar pattern ^c	Phospholipid pattern ^d	Major menaquinones ^e												Fatty acids				T
				MK-9				MK-10				MK-12								
				H ₂	H ₄	H ₆	H ₈	H ₂	H ₄	H ₆	H ₈	H ₄	H ₆	H ₈	S	U	I	A		
<i>Actinoplanes</i>	II	D	P II	V	+	V			+						+	+	+	+	-

<i>Pilimelia</i>	II	D	P II	+	+										+	+	+	V	-	

^aCompiled from: Asano et al. (1989b); Collins et al.(1984); Goodfellow and Cross (1984); Kroppenstedt (1985); Labeda et al. (1985); Lechevalier et al. (1981); Stackebrandt and Kroppenstedt (1987); Vobis (1989b). For further details and exceptions, see text.
^bCell wall chemotype II, glycine and *meso*- and/or 3-hydroxy diaminopimelic acid (A₃pm).
^cWhole cell sugar pattern D, xylose and arabinose (Lechevalier and Lechevalier, 1970b).
^dPhospholipid pattern: P I, nitrogenous phospholipid absent; P II, phosphatidylethanolamine present (Lechevalier et al., 1977).
^eS, saturated; U, unsaturated; I, iso-; A, anteiso-; T, tuberculostearic acid (10-methyl); V, variable; +, present; -, absent; ND, no data.

are characterized by cell wall chemotype II. Glycine and *meso*-diaminopimelic acid (A₂pm) and/or 3-hydroxy-diaminopimelic acid are the amino acids characteristic of the peptidoglycan. The primary structure of the peptidoglycan was described by Kawamoto et al. (1981). Glycine, rather than L-alanine, is linked to muramic acid, and *meso*-diaminopimelic acid or its hydroxylated derivative is directly cross-linked to the D-alanine of an adjacent peptide subunit: Muramic acid is *N*-glycolated. The *N*-glycolyl muramic acid is a characteristic unique to the genera with cell wall type II and was found in many *Actinoplanes* and *Ampullariella* species (Stackebrandt and Kroppenstedt, 1987). It can be easily identified by a colorimetric method (Uchida and Aida, 1977).

Deviations from the typical wall chemotype II are found in some species of *Micromonospora*, which also contain LL-diaminopimelic acid (Kawamoto et al., 1981). A further exception concerns *Actinoplanes caeruleus*, which has lysine and serine as amino acids, instead of A₂pm (Horan and Brodsky, 1986a; Tille et al., 1982). The lack of A₂pm in a morphologically incontestable *Actinoplanes* species raises a lot of taxonomical problems (Stackebrandt and Kroppenstedt, 1987).

WHOLE CELL SUGAR PATTERN The sugars used for classification are, in particular, the components of the cell wall polysaccharides. They can be detected after hydrolyzation of whole cells. Based on the pattern of diagnostic sugars, the actinomycetes containing *meso*-A₂pm can be divided into further groups (Lechevalier and Lechevalier, 1970a). In general, the actinoplanetes have wall chemotype II and the sugar pattern D in common (Table 3). The pentoses xylose and arabinose are the characteristic sugars.

Some species of *Micromonospora* also contain other diagnostic sugars, such as galactose and madurose (3-O-methyl-D-galactose) (Meyertons et al., 1987). In *Catellatospora* strains, an unusual sugar detected was 3-O-methylrhamnose (Asano et al., 1989a).

The separation of whole cell sugars is usually carried out by thin-layer chromatography (Hasegawa et al., 1983; Meyertons et al., 1987).

MYCOLIC ACIDS The cell walls of the actinoplanetes have the *N*-glycolated muramic acid type in common with those of the *Mycobacterium-Nocardia-Rhodococcus*-group (Minnikin and O'Donnell, 1984). The mycelium of this group fragments into coccoid or bacillary elements. They can also be further characterized by the presence of mycolic acids, which are not present in the *Actinoplanes* group. For routine analysis,

thin-layer chromatography is usually used (Minnikin et al., 1975).

PHOSPHOLIPIDS The composition of phospholipids is of high taxonomical value in actinomycetes in general, and five very distinct phospholipid types (P I to P V) have been observed (Lechevalier et al., 1977, 1981). Most of the genera of the actinoplanetes are of phospholipid type P II (phosphatidylethanolamine present, phosphatidylcholine and the unknown glucoseamine-containing phospholipid absent) (Table 3). However, *Glycomyces* is distinct since it has P I (phosphatidylcholine, phosphatidylethanol and the unknown glucoseamine-containing phospholipid absent) (Labeda et al., 1985). The phospholipid types are also useful taxonomic markers for separating other sporangia-forming genera with motile spores from the *Actinoplanes* group (Hasegawa et al., 1979). The unusual absence of phosphatidylethanolamine in *Ampullariella regularis* (Stackebrandt and Kroppenstedt, 1987) may indicate a peculiar variability in the phospholipid pattern in the genus *Ampullariella*.

Several methods for characterizing the phospholipids have been described (Lechevalier et al., 1977; Vitiello and Zanetta, 1978; O'Donnell et al., 1982).

MENAQUINONES Determination of the composition of menaquinones is helpful for differentiation at the genus level (Table 3). The genera *Actinoplanes*, *Ampullariella*, and many of the *Micromonospora* species contain menaquinones with 9 to 10 tetrahydrogenated isoprene side chains, MK-9 (H₄) and MK-10 (H₄), thus fitting into type 3b of the classification scheme of Kroppenstedt (1985). In *Actinoplanes auranticolor* and in *Micromonospora carbonaceae* subsp. *aurantiaca* only MK-9 (H₄) occurs (Stackebrandt and Kroppenstedt, 1987). Type 4 occurs in *Micromonospora echinospora* subsp. *pallida*, which has tetra-, hexa-, and octahydrogenated quinones with 12 isoprene units. Many other *Micromonospora* species also have type 4 menaquinones, with MK-10 (H₄) and MK-10 (H₆) (Collins et al., 1984; Kawamoto, 1989).

The menaquinone type 4b, with MK-9 (H₄), (H₆) and (H₈), is characteristic for *Dactylosporangium* species and type 4a with MK-9 (H₂) and (H₄) is characteristic for *Pilimelia* (Kroppenstedt, 1985). *Catellatospora* species have either type 4a with tetra- and hexahydrogenated menaquinones with nine isoprene units or type 4c with hexa- and octahydrogenated menaquinones with 10 units (Asano et al., 1989b). According to Labeda (1989), the genus *Glycomyces* has MK-10 (H₂) and MK-10 (H₆). In the species *Glycomyces rutgersensis*, MK-9 (H₄) could also be

detected (R. M. Kroppenstedt, unpublished observations). This indicates that the common type 3b for *Actinoplanes* and *Micromonospora* species is also present in *Glycomyces*.

FATTY ACIDS The usefulness of fatty acids as chemotaxonomical markers was demonstrated by Kroppenstedt and Kutzner (1978) and Kroppenstedt (1979). In the classification scheme developed by Kroppenstedt (1985), three main types of fatty acid pattern were proposed. Among the actinoplanetes (Table 3), the genus *Micromonospora* has a separate position with type 3b, characterized by the occurrence of 10-methyl branched fatty acids (tuberculostearic acid). Recent studies indicate that some strains of *Dactylosporangium* belong to the same type (Stackebrandt and Kroppenstedt, 1987). In general, *Dactylosporangium* species have fatty acid type 2, as is also characteristic for *Ampullariella* (type 2d) and *Actinoplanes* (type 2c): iso/anteiso branched- and monosaturated *cis*-9,10-octadecanonic acids are the predominant fatty acids (Kroppenstedt, 1985; Stackebrandt and Kroppenstedt, 1987). A similar iso/anteiso fatty acid pattern is found in *Glycomyces rutgersensis* (R. M. Kroppenstedt, unpublished observation). Members of *Pilimelia* have fatty acid type 2b with a high content of iso-C₁₅, iso-C_{15:1}, and iso-C_{17:1} fatty acids, lacking substantial amounts of C₁₈ fatty acid (Stackebrandt and Kroppenstedt, 1987).

Cultural Characteristics of the Differentiation of the Actinoplanetes Genera and Species

For subculturing new isolates, several complex agar media should be tested, including the isolation medium, because the individual strains might have quite different nutrient requirements. In our laboratory, we usually start with Emerson's yeast extract-starch agar or casamino acids-peptone-Czapek agar. Vegetative growth is also supported by Bennett agar, Hickey-Tresner agar, Czapek sucrose agar, peptone-Czapek agar, and glucose-asparagine agar. For keratinic isolates, half-concentrated skim milk agar is used (Schäfer, 1973). For the compositions of the above-mentioned media, see "Media for Isolation and Cultivation" below.

Actinoplanes ((Couch)/Palleroni, 1989)

Isolates of *Actinoplanes* form compact colonies on solid agar media (Fig. 1A and C). Aerial mycelium is usually absent or only rudimentarily

developed. Colonies can be covered with a whitish bloom, if abundant sporangia are produced on the surface of the substrate mycelium (Fig. 1B and D). The basic color of the mycelium is orange, presumably due to a carotenoid pigment (Szaniszló, 1968), but a great variety of colors exists, depending on the individual strains: cream to yellow, brown, rusty brown, red, blue, violet, green, or black (Palleroni, 1989; Vobis, 1987).

In general, sporangia develop directly on the surface of a colony (Fig. 1D, E, and F). In *A. minutisporangius*, they are also submerged (Ruan et al., 1986). Frequently, the sporangia arise terminally from "palisade" hyphae, which are thicker in diameter and vertically oriented (Bland and Couch, 1981). Inside the sporangia, the spores are arranged in coils (Fig. 1G); but in *A. rectilineatus*, they run in parallel rows (Lechevalier and Lechevalier, 1975). If the sporangial envelopes are very thin and transient, individual sporangia may be attached (Fig. 1E). The spores of *Actinoplanes* are globose or subglobose to short bacilliform and possess a tuft of flagella (Fig. 8).

Species differentiation is based on a combination of morphological and physiological characters (Palleroni, 1989). The shape of the sporangia ranges from globose, subglobose, oval, umbelliform, cylindrical, or lobate to irregular. The average size of a sporangium is from 4 to 25 µm in diameter. Extreme dimensions of sporangia exist in *A. minutisporangius*, with 2 µm as a minimum (Ruan et al., 1986) and 47 µm as a maximum (G. Vobis, unpublished observations). The unusual presence of aerial hyphae is characteristic for *A. rectilineatus*, *A. ferrugineus*, *A. garbadinensis*, and *A. teichomyceticus* (Palleroni, 1989).

The color of the mycelium is another characteristic used in species differentiation: for instance, tan to blue in *A. caeruleus* (Horan and Brodsky, 1986a), violet in *A. ianthinogenes* (Coronelli et al., 1974), and rusty brown in *A. ferrugineus* (Palleroni, 1979). Beside yellowish or brownish soluble pigments in several species, a cherry red pigment is the distinctive mark of *A. italicus* (Beretta, 1973) and a soluble blue pigment is found in *A. cyaneus* (Terekhova et al., 1977). Physiological tests like degradation, hydrolysis, coagulation, peptonization, or liquefaction of various compounds or media can also be used (Palleroni, 1989). The assimilation tests with different carbon sources, routinely carried out with sugars, were extended to many more organic compounds (Palleroni, 1979). Palleroni (1989) listed a total of 15 species for the genus, including the two members of the genus formerly called *Amorphosporangium* (Couch, 1963). Using numerical and chemical classification methods, recently the numbers of *Actinoplanes*

species could be enlarged by the description of five new species (Goodfellow et al., 1990).

Ampullariella (Couch, 1963)

The colonies of *Ampullariella* strains grown on solid agar media are often soft and can be pulled apart easily with a needle. They are elevated, with protuberances in the center of the colony. Their marginal areas can be ridged or flat (Fig. 2A). The basic orange color of the substrate mycelium is frequently overlayed by darker pigments. Depending on the individual strain, red, brown, olive or black variations can be observed. Different-colored segments may even occur in a single colony. Rudimentary aerial mycelium can be produced by several strains. Their colonies are consequently covered by a whitish gray layer.

The production of sporangia may occur in such extensive masses that the whole surface of the colony is completely covered (Fig. 2A and C). Other strains only develop a very few sporangia, which can be detected only by direct observation with the light microscope. Palisade hyphae supporting the sporangia have never been observed. The species of the genus *Ampullariella* have to be identified by the morphology of their spores and sporangia. The spores are rod-shaped and are usually four times longer than they are wide (Table 2; Fig. 2D). They have a polarly inserted tuft of flagella (Fig. 8). The spores are arranged within the sporangia in parallel rows. *A. regularis* has cylindrical or bottle-shaped sporangia, measuring $5\text{--}14 \times 8\text{--}30 \mu\text{m}$ (Fig. 2D). Pyriform or bell-shaped sporangia, sometimes with irregularly rounded protuberances at the top, can be split one or several times along the longitudinal axis (Fig. 2B and C). Such sporangia with lobes occur in *A. campanulata* ($5\text{--}15 \times 6\text{--}12 \mu\text{m}$) and in *A. lobata* ($4\text{--}20 \times 12\text{--}32 \mu\text{m}$). The sporangia of *A. digitata* are smaller ($3\text{--}9 \times 6\text{--}12 \mu\text{m}$) and very deeply split (Couch, 1963; Vobis and Kothe, 1989). Beside the morphological features, a few physiological criteria can also be used for species differentiation (Schäfer, 1973; Vobis and Kothe, 1989). Melanoid pigments are produced in *A. digitata*, which has an olive- to-black substrate mycelium. Yellowish to greenish soluble pigments occur in several strains (Couch, 1963). *A. violaceochromogenes* can be identified by the presence of a violet-to-dark purple diffusible pigment (Nonomura et al., 1979).

Eight species and subspecies of *Ampullariella* are currently known (Vobis and Kothe, 1989) although half of them are still "species incertae sedis." Whether *Ampullariella* should be a separate genus from *Actinoplanes* is unclear. The molecular systematic data favor a unification of the two genera (Stackebrandt and Kroppenstedt, 1987; Kothe, 1987), whereas following traditional

morphological concepts (Vobis, 1989a), two genera can be distinguished clearly by the shape and size of spores (Table 2; Figs. 2D and 8).

Catellatospora (Asano and Kawamoto, 1986)

Colonies of *Catellatospora* strains always produce substrate mycelium; true aerial mycelium is not developed. The color of the colonies varies from light wheat to yellow, mustard gold, orange, and reddish brown. Cultures grown on agar media that support poor growth can be crowded with short chains of spores (Fig. 3A), with 5 to 30 spores forming a chain which emerges directly from the substrate hypha (Fig. 3C). The spore chains are straight to flexuous, vertically oriented, and may be branched (Fig. 3B and D). The spores are nonmotile, cylindrical, barrel-shaped to ovoid, with smooth to slightly rough surfaces, measuring $0.6\text{--}0.8 \times 0.9\text{--}1.2 \mu\text{m}$ (Asano and Kawamoto, 1986).

In addition to spore chains, a few strains of *C. tsunoense* and *C. ferruginea* produce single spores ("globose bodies") terminally on branches of substrate hyphae (Asano et al., 1989b). These spores are morphologically very similar to the globose spores of the genus *Dactylosporangium* (Fig. 4E). In *Catellatospora*, they are $0.4\text{--}0.6 \mu\text{m}$ in diameter, whereas in *Dactylosporangium*, they are more than double that size (Table 2).

The color of the substrate mycelium, the type of menaquinone, and the presence or absence of the specific cell wall sugar 3-O-methylrhamnose are used for species differentiation (Asano et al., 1989a, 1989b). *C. citrea* and *C. tsunoense* have major menaquinones with nine isoprene units (MK-9) and yellow-colored mycelium. The species *C. ferruginea* and *C. matsumotoense* have menaquinones with 10 isoprene units (MK-10) and are usually orange to reddish brown. Their cell walls also contain 3-O-methylrhamnose, and they are resistant to novobiocin (Asano et al., 1989b). Further species differentiation can be made by the requirement for thiamine in *C. tsunoense* and *C. ferrugineae* and the requirement for methionine in *C. citrea* subsp. *methionotrophica* (Asano and Kawamoto, 1988). The utilization pattern of carbon sources also supports the differentiation into the four species and subspecies mentioned above.

Dactylosporangium (Thiemann, Pagani and Beretta, 1967)

Dactylosporangium strains form compact colonies on agar media. The colonies are mostly flat, with a smooth to wrinkled surface, and look somewhat tough and leathery. Formation of coremia may occur but true aerial mycelium is

not developed. The color of the substrate mycelium varies from pale orange to deep orange, amber, brownish with rose tinge, rose, and wine to brown or yellowish brown (Shomura et al., 1986; Vobis, 1989c).

Two completely different types of spores can be formed in *Dactylosporangium* strains: motile spores inside the sporangia and nonmotile spores, which are borne singly on substrate hyphae. The sporangia sit directly on the substrate, either singly or in bundles (Fig. 4A and B). They are finger-shaped or claviform, containing only one row of no more than four spores (Fig. 4C). The sporangiospores are variable in shape and are sometimes still connected while swimming with the aid of flagella (Fig. 8). The nonmotile, substrate spores are spherical (1.7–2.8 μm in diameter) and exhibit a typical phase-brightness (Fig. 4D). They arise terminally on short side-branches of substrate hyphae (Fig. 4E). Amorphous material can be deposited outside the spore wall (Fig. 7F). The cytoplasm includes crystalline proteins and structured bodies (Sharples and Williams, 1974). Morphologically similar globose spores may also occur in *Catellatospora* strains (Asano et al., 1989b), but they are smaller in diameter (Table 2). In *D. fulvum*, the sporangia and the globose spores may also be visible on coremia (Shomura et al., 1986).

Because of the minimal differences in morphology, chemotaxonomy, and physiology between the various *Dactylosporangium* strains, speciation is mainly based on the color of the substrate mycelium and the diffusible pigments (Vobis, 1989c). *D. aurantiacum* has orange-colored substrate mycelium without soluble pigments. The mycelium of *D. thailandense* is orange to brown, producing an amber to brown soluble pigment (Thiemann et al., 1967). *D. matsuzakiiense* also has orange colonies, but is recognizable by a light brownish-pink diffusible pigment (Shomura et al., 1980). The substrate mycelium of *D. vinaceum* is red to brown, and the soluble pigments are red to deep red (Shomura et al., 1983). *D. roseum* is characterized by a rose-colored mycelium and *D. fulvum* by a yellowish-brown-colored one (Shomura et al., 1985, 1986).

At present, eight species of *Dactylosporangium* are described, but two of them are “species incertae sedis”: *D. variesporium*” and *D. salmoneum*” (Vobis, 1989c).

Glycomyces (Labeda, Testa, Lechevalier, and Lechevalier, 1985)

Colonies of *Glycomyces* develop both substrate and aerial mycelium on agar media (Fig. 5A and B). The substrate mycelium is pale yellowish-white to tan. The aerial mycelium is white and is produced abundantly to sparsely, depending on

the medium used (Labeda, 1989). Slightly yellowish to brown colored soluble pigments can be produced (Labeda et al., 1985).

Long chains of spores are formed by fragmentation of aerial hyphae. The spores are nonmotile, cylindrical with square ends, measuring 0.5×0.7 – $1.8 \mu\text{m}$ (Fig. 5C and D).

Only two species have been described. They can be differentiated by their utilization pattern of organic compounds (Labeda, 1989). Furthermore, *G. rutgersensis* produces acid from adonitol and melibiose, whereas *G. harbinensis* does not (Labeda et al., 1985).

The glycolipid-containing genus *Glycomyces* is tentatively classified within the *Actinoplanes* group because of the chemotaxonomic similarities in the composition of the cell wall, the menaquinones, and the fatty acids (R.M. Kroppenstedt, unpublished observations), but because it has phospholipid type P I instead of type P II, its position remains exceptional among the actinoplanetes (Table 3). Phospholipid type P I is characteristic of the genus *Actinomadura* and of some species of *Microtetraspora* and *Nocardioidea*. This correlates with the production of true aerial mycelium and of nonmotile spores in chains, which *Glycomyces* has in common with the above-mentioned genera, but not with the actinoplanetes.

Micromonospora (Bokov, 1923)

Colonies growing on solid media form only substrate mycelium, which is raised and folded (Fig. 6A). Some strains can develop short, sterile aerial hyphae, giving a pruinose surface. The color of young colonies is pale yellow to light orange, becoming deep orange, red, purple, brown, or blue-green with age, depending on the individual strain (Kawamoto, 1989). The upper mycelial layers may burst open (Fig. 6B and D) or may be completely covered by a mucous mass of spores, giving the colonies bright brown-black, green-black, or black-colored surfaces (Fig. 6C). Other strains produce the spores accumulated in distinct areas on the surface (Fig. 6B) or completely immersed in the substrate (Fig. 6D).

The spores of *Micromonospora* are formed singly on substrate mycelium (Fig. 6E). They are nonmotile, and spherical to oval in shape, with a diameter of 0.7 – $1.5 \mu\text{m}$. The sporophores, often together in clusters, produce spores terminally on short hyphal branches (Luedeman and Casmer, 1973). The spore surfaces of almost all species have blunt-spiny projections (Kawamoto, 1989).

The description of many species of this genus began with the taxonomical studies of the gentamicin-producing *Micromonospora* strains (Luedeman and Brodsky, 1964). More than 12

species and subspecies could be listed recently (Kawamoto, 1989). The species concept is based on chemotaxonomical markers, pigment production, and physiological characteristics. The presence or absence of the 3-hydroxy- A_2pm isomer in the peptidoglycans of the cell walls divides the genus into two species groups (Kawamoto et al., 1981). The predominant menaquinones of *M. carbonacea* and *M. halophytica* have nine isoprene units (MK-9) and those of *M. echinospora* subsp. *pallida* have 12 units (MK-12). All the other remaining species have MK-10 menaquinones (Collins et al., 1984; Kawamoto, 1989).

Mycelial pigments are also of diagnostic value: *M. coerulea* has a blue-green colored mycelium. *M. echinospora* subsp. *echinospora* and subsp. *ferruginea* have a maroon-purple pigment in the substrate mycelium. The following species are characterized by soluble pigments of various colors: *M. halophytica* subsp. *halophytica* (red-brown), *M. chalcea* (yellow), *M. purpureochromogenes* and *M. olivasterospora* (olive-green), and *M. rosaria* (wine-red) (Horan and Brodsky, 1986b; Kawamoto, 1989). Further physiological parameters, such as growth on special media, carbon utilization profiles, glycosidase activity, nitrate reduction, and NaCl tolerance, support the identification of species and subspecies (Kawamoto, 1989).

Pilimelia (Kane, 1966)

Strains of *Pilimelia* only form small, compact colonies, which are about 5 mm in diameter after 4 weeks of incubation. Growth is supported by keratinic substances like hair (Fig. 7A) and cattle-horn meal (Vobis, 1984). Aerial mycelium is not developed. The color of the substrate mycelium ranges from pale to lemon yellow, yellow-gray, and golden yellow to orange (Vobis, 1989b).

The sporangia are developed directly on the surface of agar medium or on natural substrates (Fig. 7B). The shape of the sporangia is globose, ovoid, pyriform, campanulate, or cylindrical and approximately 10–15 μm in size. In some strains, each sporangium contains up to a thousand spores (Fig. 7F). The spores are rod like to reniform, equipped with a laterally inserted tuft of flagella (Fig. 8). Nonmotile spores (“conidia”) may be also produced (Fig. 7E).

Species differentiation for *Pilimelia* is based on morphological and colonial characters. *P. ter-evasa* has spherical to campanulate sporangia with parallel rows of abundantly branched spore chains (Fig. 7B and F). The colonies have a soft consistency and are yellow to yellow-gray. *P. anulata* has cylindrical sporangia (Fig. 7E). The top segment of the sporangiophore is expanded to

form a small ring-like structure (“annulus”) (Fig. 7D). The mycelium has a yellowish color and is soft and pasty. In contrast, the colonies of *P. columellifera* are very solid and spherical to pyriform sporangia are produced, with the spore chains inside arranged in swirls (Vobis, 1984). The sporangiophores are unseptate and reach into the lumen of the sporangium, where they are visible as small columns (Fig. 7C). The substrate mycelium of *P. columellifera* is either golden yellow to orange or colorless to pale brownish in the subspecies *pallida* (Vobis et al., 1986).

Pilimelia strains were considered for a long time to be keratinophilic members of *Ampullariella*, but recent studies on the chemotaxonomy, ultrastructure, and physiology of the three species (Vobis, 1989b) have supported recognition of them as a separate genus (Kroppenstedt, 1979; Schäfer, 1973; Vobis et al., 1986).

Media for Isolation and Cultivation

The recipes for the media used for isolation, sporulation, and vegetative growth are listed below. However, the media developed by the “International Streptomyces Project” (Shirling and Gottlieb, 1966) are not included. Routine sterilization is carried out at 121°C for 15 to 20 min by autoclaving. The vitamins and the antibiotic agents are separately sterilized by filtration and added to cooled (50°C) agar media. If necessary, after autoclaving, the pH should be adjusted with sterile acid or base.

Additions to the Agar Media

ANTIBIOTICS Many isolation media contain antifungal or antibacterial agents. The concentrations and/or combinations of these supplements are given in Table 1, in the text, or in the corresponding recipes. To dissolve cycloheximide, warm water (45°C) is recommended (Hunter-Cevera et al., 1986). Nystatin can be dissolved initially in dimethylsulfoxide and then diluted in 95% alcohol (Makkar and Cross, 1982). As nystatin is not totally soluble in water at pH 7.0 and is unstable at high pH, the pH of the aquatic solution can be increased with 1 M NaOH to 11.0, filter sterilized, and immediately lowered to 7.0 with HCl (Hunter-Cevera et al., 1986).

VITAMINS Some media require the addition of B vitamins (Nonomura and Ohara, 1969; Hayakawa and Nonomura, 1987; Shearer, 1987). The amounts indicated below are per liter of the corresponding medium.

B-Vitamins (Nonomura and Ohara, 1969)

Thiamine hydrochloride	0.5 mg
Riboflavin	0.5 mg
Niacin	0.5 mg
Pyridoxine hydrochloride	0.5 mg
Inositol	0.5 mg
Calcium pantothenate	0.5 mg
<i>para</i> -Aminobenzoic acid	0.5 mg
Biotin	0.25 mg

Recipes for Agar Media

The quantities below are all per liter of distilled water, unless otherwise stated.

Arginine Glycerol Salts Agar (El-Nakeep and Lechevalier, 1963)

Arginine monohydrochloride	1.0 g
Glycerol (specific gravity not less than 1.249 at 25°C)	12.5 g
K ₂ HPO ₄	1.0 g
MgSO ₄ · 7H ₂ O	0.5 g
Fe ₂ (SO ₄) ₃ · 6H ₂ O	0.01 g
CuSO ₄ · 5H ₂ O	0.001 g
ZnSO ₄ · 7H ₂ O	0.001 g
MnSO ₄ · H ₂ O	0.001 g
Agar	15.0 g

Adjust to pH 6.9 to 7.1.

Arginine Vitamin Agar (Nonomura and Ohara, 1969)

L-Arginine	0.3 g
Glucose	1.0 g
Glycerol	1.0 g
K ₂ HPO ₄	0.3 g
MgSO ₄ · 7H ₂ O	0.2 g
NaCl	0.3 g
Fe ₂ (SO ₄) ₃	10.0 mg
MnSO ₄ · 7H ₂ O	1.0 mg
CuSO ₄ · 5H ₂ O	1.0 mg
ZnSO ₄ · 7H ₂ O	1.0 mg
Agar	15.0 g

Adjust to pH 6.4, and then add:

B-Vitamins	(see above)
Cycloheximide	50.0 mg
Nystatin	50.0 mg

Artificial Soil Agar (Henssen and Schäfer, 1971)

CaSO ₄ · 2H ₂ O	1.01 g
Ca(NO ₃) ₂ · 4H ₂ O	0.49 g
MgSO ₄ · 7H ₂ O	0.70 g
K ₂ SO ₄	0.025 g
K ₂ HPO ₄	0.005 g
NaHCO ₃	0.2 g
FeCl ₃	trace
Yeast extract	0.1 g
Glucose	0.01 g
Soil extract	50 ml
Agar	15.0 g

Adjust to pH 6.6 to 6.8.

To prepare soil extract, equal volumes of leafy soil and tap water are boiled for 2 hours and then cleared by centrifugation.

Bennett's Agar (Waksman, 1961)

Glucose	10.0 g
Yeast extract	1.0 g
Beef extract	1.0 g
N-Z-Amine A (casein digest; Sheffield Farms Co.)	2.0 g
Agar	15.0 g

Adjust to pH 7.3.

Bennett's Agar (Modified) (Wakisaka et al., 1982)

Glucose	10.0 g
Casamino acids	2.0 g
Yeast extract	2.0 g
Beef extract	1.0 g
Agar	15.0 g

Adjust to pH 7.3, and then add:

Cycloheximide	30.0 mg
---------------	---------

Casamino Acids-Peptone-Czapek Agar (Henssen and Schäfer, 1971)

Casamino acids	1.0 g
Peptone	2.0 g
K ₂ HPO ₄	1.0 g
KCl	0.5 g
MgSO ₄ · 7H ₂ O	0.5 g
FeSO ₄ · 7H ₂ O	0.01 g
Sucrose	30.0 g
Agar	15.0 g

Adjust to pH 7.0.

Calcium Malate Agar (Waksman, 1961)

Glycerol	10.0 g
Calcium malate	10.0 g
NH ₄ Cl	0.5 g
K ₂ HPO ₄	0.5 g
Agar	15.0 g

Adjust to pH 7.0.

Colloidal Chitin Agar (Composition of Minerals According to Willoughby, 1968)

Colloidal chitin (dry weight)	2.0 g
CaCO ₃	0.02 g
FeSO ₄ · 7H ₂ O	0.01 g
KCl	1.71 g
MgSO ₄ · 7H ₂ O	0.05 g
Na ₂ HPO ₄ · 12H ₂ O	4.11 g
Agar	18.0 g

Adjust to pH 7.0.

Collodial Chitin Agar (Composition of Minerals According to Hsu and Lockwood, 1975)

Collodial chitin (dry weight)	2.0 g
K ₂ HPO ₄	0.7 g
KH ₂ PO ₄	0.3 g
MgSO ₄ · 5H ₂ O	0.5 g
FeSO ₄ · 7H ₂ O	0.01 g
ZnSO ₄	0.001 g
MnCl ₂	0.001 g
Agar	20.0 g

Adjust to pH 7.0.

Preparation of Colloidal Chitin (Makkar and Cross, 1982)

Crude chitin is washed alternately in 1 N NaOH and 1 N HCl for 24-h periods each, five times. Then, it is washed four times with 95% (v/v) ethanol. 15 g of the purified white chitin is dissolved with 100 ml of concentrated HCl and stirred in an ice bath for 20 min. The mixture is filtered through glass wool, and the solution is poured into cold distilled water to precipitate the chitin. The insoluble chitin on the glass wool is treated again with HCl, and the process is repeated until no more precipitate is obtained when the filtrate is added to cold water. The colloidal chitin is allowed to settle overnight and the supernatant is decanted. The remaining suspension is neutralized to pH 7.0 with NaOH. The precipitated chitin is centrifuged, washed, and stored as a paste at 4°C.

Various other procedures for preparing colloidal chitin can be found in Willoughby (1968), Hsu and Lockwood (1975), Johnston and Cross (1976), and Hunter-Cevera et al. (1986).

Czapek Sucrose Agar (Bland and Couch, 1981)

Sucrose	30.0 g
NaNO ₃	3.0 g
K ₂ HPO ₄	1.0 g
MgSO ₄ · 7H ₂ O	0.5 g
KCl	0.5 g
FeSO ₄	0.01 g
Agar	15.0 g

Adjust to pH 7.0 to 7.3.

Emerson's Yeast Extract-Starch Agar (Emerson, 1958)

Yeast extract	4.0 g
Soluble starch	15.0 g
K ₂ HPO ₄	1.0 g
MgSO ₄ · 7H ₂ O	0.5 g
Agar	20.0 g

Gause Number 1 Agar (Gause, 1958)

KNO ₃	1.0 g
K ₂ HPO ₄	0.5 g
MgSO ₄	0.5 g
NaCl	0.5 g
FeSO ₄	0.01 g
Starch	20.0 g
Agar	30.0 g
Tap water	1 liter

Glucose Asparagine Agar (Gordon and Smith, 1955)

Glucose	10.0 g
Asparagine	0.5 g
K ₂ HPO ₄	0.5 g
Agar	15.0 g

Adjust to pH 6.8.

Hickey-Tresner Agar (Waksman, 1961)

Dextrin	10.0 g
Yeast extract	1.0 g
Beef extract	1.0 g
N-Z-Amine A (casein digest; Sheffield Farms Co.)	2.0 g
CoCl ₂ · 7H ₂ O	0.02 g
Agar	20.0 g

Adjust to pH 7.3.

Humic Acid-Ion Agar (Willoughby et al., 1968)

5 g of humic acid in solid form (see below) is dissolved in 10 ml of 0.2 N NaOH, and the solution is made up to 1 liter with distilled water; pH 7.0 to 7.3. Then 20 g of agar (Oxoid Ionagar No. 2) is added.

Preparation of Humic Acid (Willoughby et al., 1968):

Air-dried (90°C for 24 hours) peat from a blanket bog or from compacted, decomposing tree leaves (oak and alder) is first extracted with acetone for 3 hours and then redried at 50°C overnight. The humic acids are extracted from the material (100 g) with 2 liters of 0.2 N NaOH by shaking occasionally, standing overnight at room temperature, and filtering off the insoluble residue on a no. 4 sintered glass funnel. The filtrate is acidified to pH 1.0 with concentrated HCl. The resulting precipitate is centrifuged off, washed twice with water, and left overnight at -20°C to freeze. After thawing, the now-granular particles are filtered off from the remaining liquors, washed, and air-dried at 50°C.

Humic Acid-Vitamin Agar (Hayakawa and Nonomura, 1987)

Humic acid (see below)	
(dissolved in 10 ml of 0.2 N NaCl)	1.0 g
Na ₂ HPO ₄	0.5 g
KCl	1.71 g
MgSO ₄ · 7H ₂ O	0.05 g
FeSO ₄ · 7H ₂ O	0.01 g
CaCO ₃	0.02 g
Agar	18.0 g

Adjust to pH 7.2, and then add:

B Vitamins (see above)

Cycloheximide	50.0 mg
---------------	---------

Preparation of Humic Acid (Hayakawa and Nonomura, 1987)

500 g of soil sample (A-horizon of a forest) is suspended in 1 liter of 0.5% NaOH solution and left standing at room temperature for 24 hours, with occasional stirring. The precipitate of the suspension is removed by centrifugation (20 min at 7,000 rpm), and the supernatant is acidified to pH 1.0 with concentrated HCl. The resulting precipitate is centrifuged (20 min at 3,000 rpm), washed three times by centrifugation with 150 ml of water and suspended again in 150 ml of water. The suspension is frozen overnight at -20°C. After thawing, the granulated humic acid is filtered, washed, and air-dried.

Kadota's Cellulose Benzoate Agar (Sandrak, 1977)**1) Basal medium Sodium benzoate**

NaNO ₃	0.5 g
K ₂ HPO ₄	1.0 g
MgSO ₄ · 7H ₂ O	0.5 g
FeSO ₄ · 7H ₂ O	0.01 g
Sodium benzoate	20.0 g
Agar	20.0 g

Adjust to pH 7.2

2) Cellulose powder (0.67g) is mixed with 1 ml soil suspension and 2 ml liquid basal medium before inoculation of the plates.

M3 Agar Medium (Rowbotham and Cross, 1977)

KH ₂ PO ₄	0.466 g
Na ₂ HPO ₄	0.732 g
KNO ₃	0.10 g
NaCl	0.29 g
MgSO ₄ · 7H ₂ O	0.10 g
CaCO ₃	0.02 g
Sodium propionate	0.20 g
FeSO ₄ · 7H ₂ O	200 µg
ZnSO ₄ · 7H ₂ O	180 µg
MnSO ₄ · 4H ₂ O	20 µg
Agar	18.00 g

Adjust to pH 7.0, and then add:

Cycloheximide	50.0 mg
Thiamine hydrochloride	4.0 mg

Oatmeal-Soil Extract Agar (Shearer, 1987)

Oatmeal agar (Difco)	5.5 g
Agar	16.0 g
Soil extract	500 ml
Deionized water	500 ml

Adjust to pH 7.2.

Peptone-Czapek Agar (Bland and Couch, 1981)

Sucrose	30.0 g
Peptone	5.0 g
K ₂ HPO ₄	1.0 g
MgSO ₄ · 7H ₂ O	0.5 g
KCl	0.5 g
FeSO ₄ · 7H ₂ O	0.01 g
Agar	15.0 g

Adjust to pH 7.3.

Skim Milk Agar (Gordon and Smith, 1955)

Solution a:

Skim milk powder	50 g
Distilled water	500 ml

Solution b:

Agar	20 g
Distilled water	500 ml

Solutions a and b are autoclaved separately, cooled, and mixed at 45°C, and the pH is adjusted to 7.2.

Skim Milk-Cattle Hornmeal Agar (Vobis, 1984)

Solution a:

Cattle hornmeal (powdered)	10.0 g
Ca(NO ₃) ₂ · 4H ₂ O	0.5 g
MgSO ₄ · 7H ₂ O	0.7 g
K ₂ HPO ₄	0.005 g
NaHCO ₃	0.2 g
FeCl ₃	trace
Agar	20.0 g
Distilled water	900 ml

Solution b:

Skim milk powder	2.5 g
Distilled water	100 ml

Solutions a and b are autoclaved separately, cooled, and mixed at 48°C, and the pH is adjusted to 7.2.

Soil Extract Agar (Makkar and Cross, 1982)

First 150 g of garden soil is stirred in 600 ml of tap water, filtered immediately through Whatman No. 1 filter, and made up to 1 liter with tap water. To this is added:

Agar 18.0 g

Adjust to pH 7.2, and then add:

Cycloheximide	50 mg
Nystatin	50 mg

Starch-Casein-Nitrate Agar (Küuster and Williams, 1964)

Starch	10.0 g
Casein (Difco, vitamin-free)	0.3 g
KNO ₃	2.0 g
NaCl	2.0 g
K ₂ HPO ₄	2.0 g
MgSO ₄ · 7H ₂ O	0.05 g
CaCO ₃	0.02 g
FeSO ₄ · 7H ₂ O	0.01 g
Agar	18.0 g

Adjust to pH 7.0 to 7.2.

Hunter-Cevera et al. (1986) added:

Cycloheximide	75 mg
Nystatin	75 mg

Shearer (1987) added:

B-Vitamins (see above)

Starch-Casein Sulfate Agar (Palleroni, 1980)

K ₂ HPO ₄	0.5 g
MgSO ₄ (anhydrous)	5.0 g
Soluble starch	10.0 g
Casein (dissolved in diluted NaOH)	1.0 g
Agar	15.0 g

Adjust to pH 7.0 to 7.5.

Thin Pabulum Agar (Hunter-Cevera et al., 1986)

Pabulum (boiled in cheesecloth for 20 to 30 min)	7.5 g
Agar	15.0 g
Tap water	1 liter

Adjust to pH 6.8 to 7.0, and then add:

Cycloheximide	75 mg
Nystatin	75 mg

Water Agar (Hunter-Cevera et al., 1986)

Tap water	1 liter
Crude agar flakes	17.5 g

Adjust to pH 6.8, and then add:

Cycloheximide	75 mg
Nystatin	75 mg

Applications

Many members of the actinoplanete genera produce useful enzymes and secondary metabolites, so they may have important applications in industry, biotechnology, and agriculture. For example, vitamin B₁₂ can be produced by a

Micromonospora strain (Florent and Ninet, 1979), and strains of *Actinoplanes* and *Micromonospora* can be used for the bioconversion of complex compounds (Okami and Hotta, 1988; Boek et al., 1988). Applications which have been established already or might be used commercially in the future are described below.

Glucose Isomerase in the Food Industry

The enzyme glucose isomerase, which is primary a xylose isomerase, can be obtained from strains of *Actinoplanes*, *Ampullariella* and *Micromonospora*, in addition to strains of *Streptomyces*, *Bacillus*, and *Arthrobacter* (Crueger and Crueger, 1982; Peczyńska-Czoch and Mordarski, 1988). The glucose isomerase converts D-glucose into D-fructose and is used commercially in the starch industry to obtain high-fructose corn syrup (Aunstrup et al., 1979). Starting from about 95% glucose syrup, a twice sweeter fructose syrup is produced which is usually composed of 53% of D-glucose, 42% of D-fructose, and 5% of oligosaccharides (Crueger and Crueger, 1982).

Actinoplanes missouriensis strain ATCC 14538 produces an intracellular, soluble glucose isomerase with a molecular weight of about 80,000 daltons. The optimal pH of the enzyme is 7.0 at temperatures between 60 and 65°C. A requirement for cobalt ions for optimal activity is eliminated if the proper amount of magnesium ions is used (Gong et al., 1980). The xylose isomerase of *Ampullariella* strain ATCC 31354 exhibits superior thermostability and activity over a wide range of conditions. However, the strain itself is difficult to use as a production organism, which makes it desirable to clone and express its enzyme in a more convenient microorganism (Saari et al., 1987).

Inhibitors of α -Glucosidase as Pharmaceutical Drugs

In the course of screening for inhibitors of amylases and other mammalian intestinal carbohydrate-splitting enzymes, strains of *Actinoplanes* exhibited higher amounts of activity than did those of *Streptomyces* and *Streptosporangium* (Frommer et al., 1979). Applied orally together with food carbohydrates like starch and other oligosaccharides, these glycoside hydrolase inhibitors slow down oligosaccharide decomposition and reduce or avoid postprandial hyperglycemia and hyperinsulinemia of type IV. Therefore, they may be useful to treat metabolic illnesses such as diabetes mellitus, adipositas, and hyperlipoproteinaemia (Truscheit et al.,

1981; Creutzfeldt, 1988). Pseudooligosaccharides with an essential core consisting of an unsaturated cyclitol and 4-amino-4,6-dideoxyglucose are the most important group of α -glucosidase inhibitors. In culture filtrates of the *Actinoplanes* strain SE 50, a very effective pseudotetrasaccharide with the generic name "acarbose" could be found. This low-molecular-weight compound is stable to acid, alkali, and heat treatment and exhibits pronounced inhibition of sucrase, maltase, and amylase (Truscheit et al., 1981).

Antibiotics

The "rare" actinomycetes (i.e., nonstreptomycetes) have become increasingly interesting in the search for new active secondary metabolites (Nara et al., 1977; Okami and Hotta, 1988). In 1984, the number of known antibiotic compounds produced by all the actinomycetes together amounted to about 4,200 (Bérdy, 1984), and the proportion produced by actinoplanetes (*Micromonospora*, *Actinoplanes*, *Dactylosporangium*, and *Ampullariella*) increased from less than 1% in the year 1966 up to 10% in 1984 (Lechevalier and Lechevalier, 1967; Wagman and Weinstein, 1980; Bérdy, 1984). As can be seen in Table 4, each actinoplanetes genus covers only a part of all the chemical groups of antibiotics that are known from the genus *Streptomyces*. But they complement one another, so only the β -lactam antibiotics seem to be absent. Until now, members of *Catellatospora* and *Pilimelia* have not been included to any extent in antibiotic screening procedures.

ACTINOPLANES More than 120 antibiotics are known from *Actinoplanes* species. The most common are peptides/depsipeptides, polyene-type macrolides, and aromatic compounds, whereas the aminoglycosides, streptothricins, macrolides, and ansamycine seem to be absent (Table 4). About 50% of the antibiotics found in *Actinoplanes* are amino acid derivatives. The proline antimetabolite L-acetidine-2-carboxylic acid could be isolated from *A. ferrugineus*. This amino acid has not been found in any other prokaryotes and has only been found in eukaryotes (Palleroni, 1979). Additional amino acid derivatives are 5-azacytidin, azaserine, and the chromopeptide actinomycin, which are all properly typical *Streptomyces* antibiotics (Torikata et al., 1978). They are active as antitumor agents. The polypeptides generally exhibit activity against Gram-positive bacteria. The acidic peptide 41.012 is also an agent against mycobacteria (Celmer et al., 1977). The antibiotics A-10947, A-7413, taitomycin, and gardimicin are sulfur-

Table 4. Antibiotic groups produced by the genera of the actinoplanetes and by the streptomycetes.

Genus	Aminoglycoside	Macrolide	Ansamacrolide	β -Lactam	Peptide	Glycopeptide	Anthracycline	Tetracycline	Nucleoside	Polyene	Quinone
<i>Actinoplanes</i>					+	+			+	+	+
<i>Ampullariella</i>							+		+		
<i>Catellatospora</i>											
<i>Dactylosporangium</i>	+	+			+			+	+	+	
<i>Glycomyces</i>					+						
<i>Micromonospora</i>	+	+	+		+		+		+		+
<i>Pilimelia</i>											
<i>Streptomyces</i>	+	+	+	+	+	+	+	+	+	+	+

Data mainly based on Okami and Hotta (1988) and Nara et al. (1977); the additions made are discussed in the text.

containing polypeptides; the latter two are also active against anaerobic bacteria (Yaginuma et al., 1979; Parenti and Coronelli, 1979). The cyclic polypeptides A/287 and mycoplanecin show growth-promoting and antituberculosis effects, respectively (Hamill and Stark, 1974; Nakajima et al., 1983). The depsipeptide antibiotic plauracins A 17002 and A 2315 belong to the virginiamycin group, composed of a mixture of macrocyclic lactones and depsipeptides. They can be used for growth promotion in chicken, swine, and ruminants (Hamill and Stark, 1975; Parenti and Coronelli, 1979).

A well-studied example of the antifungal polyenic macrolides is the antibiotic 67-121 (Sch 16656). It is a complex of four polyene heptaenes produced by *A. caeruleus* (Horan and Brodsky, 1986a). It is also produced by *A. azureus*, a strain which also produces the plauracins (Parenti and Coronelli, 1979).

Some metabolites belonging to various other chemical groups are also found in strains of *Actinoplanes*. Purpuromycin is a naphthoquinone antibiotic of the rubromycin type, effective against bacteria and fungi (Coronelli et al., 1974). *A. teichomyceticus* produces the glycopetide teicoplanin (formerly called teichomycin A₂), which is composed of six factors. It belongs to the vancomycin family (Malabarba et al., 1984). The same strain also produces a phosphorus-containing glycolipid (teichomycin A₁). Both carbohydrate antibiotics are active against Gram-positive bacteria (Parenti et al., 1978). The recently described polycyclic xanthenes actinoplanone A and B were found to be potent cytotoxins in in vitro assays with HeLa cells (Kobayashi et al., 1988).

Some chemical novelties have been detected in *Actinoplanes* strains. For example, chuangxinmycin, clinically effective in cases of septicemia and urinary and biliary infections caused by *Escherichia coli*, is a completely new antibiotic composed of an unique bicyclic system formed of an indole nucleus fused to a thiopyran residue (Parenti and Coronelli, 1979). The antibiotic A/15104 Y is a chlorophenol derivative, active against bacteria and fungi. It represents the first example of a halogenated pyrrole from actinomycetes; the other biological sources have been sponges and pseudomonads (Cavalleri et al., 1978).

AMPULLARIELLA Only a dozen antibiotics are known to be produced by *Ampullariella* strains. Nevertheless, they exhibit quite a range of different chemical structures and antibiotic effects. Viriplanin is an anthracyclic antibiotic isolated from *A. regularis*, which shows activities against herpes simplex viruses (Hütter et al., 1986). The neplanecins are nucleosides produced by

another *A. regularis* strain. They are antitumor antibiotics with additional activities against phytopathogenic fungi (Yaginuma et al., 1981). Another antifungal antibiotic, candiplanecin, could be isolated from *A. regularis* subsp. *man-nitophila* (Itoh et al., 1981).

DACTYLOSPORANGIUM At present, about 30 antibiotics are known from *Dactylosporangium* strains, belonging to several chemical divisions (Table 4). As with *Micromonospora*, the major antibiotics seem to be aminoglycosides. Dactimicin is produced by *D. matsuzakiense* and *D. vinaceum* (Shomura et al., 1980, 1983). The closely related aminoglycosides gentamicin, sisomicin, fortimicin, and antibiotic G-367 could also be isolated. Another carbohydrate antibiotic is known from *D. roseum*, namely the orthosomycine complex SF-2107 (Shomura et al., 1985). All the above-mentioned antibiotics are generally active against Gram-positive and Gram-negative bacteria. Capreomycin, a polypeptide compound previously known from *Streptomyces capreolus*, could be obtained also from *D. variesporium*. It is of primary interest for its use as an antituberculosis agent (Tomita et al., 1977). *D. salmoneum* produces the polyether antibiotic compound 44,161, which is useful for the control of coccidiosis in poultry and improving feed efficiency in ruminants (Celmer et al., 1978).

The tetracycline antibiotic compound Sch 34164 (Patel et al., 1987) and the macrolide tiacumicin (Hochlowski et al., 1986) have been isolated from other *Dactylosporangium* species, suggesting that the capacity for producing antibiotic metabolites in this genus may be very large.

Glycomyces *Glycomyces harbinensis* produces the amino acid derivative azaserine and the antibiotic LL-D05139-beta (Labeda, 1989). No other antibiotics have been identified in any *Glycomyces* strains so far.

Micromonospora Among the antibiotics produced by actinoplanete genera, those of *Micromonospora* occupy the most important commercial position (Crueger and Crueger, 1982). An intensive screening of *Micromonospora* species as sources for new antibiotics began in 1963 with the discovery of gentamicin. Over 300 different antibiotics have been described (Bérdy, 1984), and the range of chemical structures is quite large (Table 4). Examples include the aminoglycosides, represented by gentamicins, sisomicin, and verdamicin; the antibiotics G-52, G-418, and JI-20; mannosidostreptomycin; kanamycin; neomycin B (antibiotic 460); sagamicin (gentamicin C_{2b}); paromamine;

fortimicins; and antibiotics 66–40 and SF 1854 (Nara et al., 1977; Wagman and Weinstein, 1980). The macrolides comprise megalomycins, rosaramicin, juvenimicins, the M-4365 complex, erythromycins, and antibiotic XK 41-B-2. Examples for ansa macrolides (ansamycins) are halomicins, rifamycins, and compound 32656. Bottromycin, microsporin, the 70591 complex, and actinomycin should be cited as representatives of the peptide antibiotics. Other miscellaneous antibiotics isolated from *Micromonospora* species include the oligosaccharides everninomycin and antlermicin, the nucleosides PA-1322 and XK-101–2, and the quinone PA-2046 (Wagman and Weinstein, 1980).

Aminoglycosides of *Micromonospora* show antibiotic effects against both Gram-positive and Gram-negative bacteria and have been introduced into clinical practice. The gentamicins C₁, C_{1a}, and C₂ are produced by *M. purpurea* and *M. echinospora* and exhibit excellent activity against *Staphylococcus aureus* and species of *Pseudomonas* and *Proteus*. Because of their vestibular and nephrotoxicity, they are used in human therapy only for severe infections (Wagman and Weinstein, 1980; Crueger and Crueger, 1982; Lancini and Parenti, 1982). Sisomycin and fortimicins, derived from *M. inyonensis* and *M. olivoasterospora*, respectively, have a similar spectrum of effectivity as gentamicin and can be used against gentamicin-resistant organisms (Wagman and Weinstein, 1980).

Biological Control in Agriculture

Reports of hyperparasitism by actinoplanetes on parasitic *Peronosporales* and *Saprolegniales* demonstrate a possible biological control of serious diseases of economic plants (Lechevalier, 1988). The oospores of pink rot causing *Phytophthora megasperma* var. *sojae* or f. sp. *glycinea* can be parasitized by certain strains of *Actinoplanes*, *Ampullariella*, and *Micromonospora* (Sneh et al., 1977). The hyphae of *Actinoplanes missouriensis* penetrate the walls of the oogonia and the oospores without forming appressoria or haustoria or changing the morphological and internal structures of the oospores (Sutherland et al., 1984). In greenhouse experiments, the root rot of soybeans caused by *Phytophthora* could be reduced by *Actinoplanes missouriensis*, *A. utahensis*, and *Micromonospora* sp. (Filinow and Lockwood, 1985).

Acknowledgments. I wish to thank Dr. H.-W. Kothe (Burlington), Dr. R. M. Kroppenstedt (Braunschweig), Dr. H. Prauser (Jena), Dr. G. S. Saddler (Gerezano), Prof. Dr. O. Salcher

(Wuppertal), Dr. J.-J. Sanglier (Basel), and Dr. J. Wink (Frankfurt) for helpful cooperation.

The Family Actinosynnemataceae

DAVID P. LABEDA

Introduction and Phylogenetic Position

The family Actinosynnemataceae (Labeda and Kroppenstedt, 2000), as currently defined by phylogenetic studies based on the analysis of 16S rDNA sequences, contains the genera *Actinokineospora* (Hasegawa, 1988), *Actinosynnema* (Hasegawa et al., 1978), *Lechevalieria* (Labeda et al., 2001), *Lentzea* (Yassin et al., 1995; Labeda et al., 2001) and *Saccharothrix* (Labeda et al., 1984; Labeda and Lechevalier, 1989a). This family lies within the suborder Pseudonocardiales in the class Actinobacteria (Stackebrandt et al., 1997). Earlier phylogenetic studies (Embley et al., 1988; Warwick et al., 1994) proposed that the genus *Saccharothrix* was associated with the family Pseudonocardiaceae, but this affiliation was not supported statistically in phylogenetic analyses, and diagnostic chemotaxonomic characteristics of *Saccharothrix* species were different from those of taxa whose placement in the Pseudonocardiaceae was well supported.

The genera included in the family Actinosynnemataceae share similar chemotaxonomic characteristics and exhibit a diagnostic whole cell sugar pattern (i.e., galactose, rhamnose and mannose are diagnostic sugars) distinct from the pattern observed for the taxa within the family Pseudonocardiaceae (i.e., arabinose and galactose). The family Actinosynnemataceae forms a coherent group (Fig. 1) within the actinobacterial phylogenetic tree calculated from ribosomal DNA sequences (Labeda and Kroppenstedt, 2000), and on the basis of current data, forms a lineage separate from, but phylogenetically closest to, the Pseudonocardiaceae. Moreover, a diagnostic nucleotide signature pattern of TA (823–975), GC (824–874) is observed in the 16S rDNA sequence for all taxa within the family Actinosynnemataceae.

Within the suborder, related genera (phylogenetically not quite within this family, but which share some properties with family members) include *Actinoalloteichus*, *Crossiella*, *Kutzneria* and *Streptoalloteichus*. These genera may well

represent another family within the suborder Pseudonocardiales, but insufficient taxa have been isolated and described to provide adequate data for resolution of their actual phylogenetic position.

The genera currently circumscribed by the family Actinosynnemataceae are all aerobic, catalase positive, non-acid-fast, and lysozyme resistant. Their common chemotaxonomic properties include type III cell wall composition (meso-diaminopimelic acid), whole cell sugar pattern consisting of galactose (in the absence of significant quantities of arabinose) along with varying quantities of rhamnose and mannose, a PII phospholipid profile typically displaying a significant amount of phosphatidylethanolamine, and menaquinones containing nine isoprenoid units (MK-9). The Actinosynnemataceae exhibit a range of morphological and physiological properties, including spore motility (expressed by several genera). Representatives of the family have been primarily isolated from soil or plant material, but their role in these environments is unclear. Some taxa have also been isolated from human or animal sources, but their capacity to cause infection or disease has not been confirmed.

Description of Genera

The genus *Actinokineospora* was described by Hasegawa (1988) to contain a single species, *Actinokineospora riparia*, which produces short aerial mycelia that fragment into motile arthrospores, but exhibit no sporangial structures. Subsequently, Tamura et al. (1995) isolated and described four additional species, *Actinokineospora diospyrosa*, *Actinokineospora globicatena*, *Actinokineospora inagensis* and *Actinokineospora terrae*, from soil and fallen leaves collected in the Yamanashi Prefecture of Japan; these species exhibit the same capacity to produce motile arthrospores from fragmentation of the aerial mycelia.

Hasegawa et al. (1978) described the genus *Actinosynnema* to contain actinomycetes that

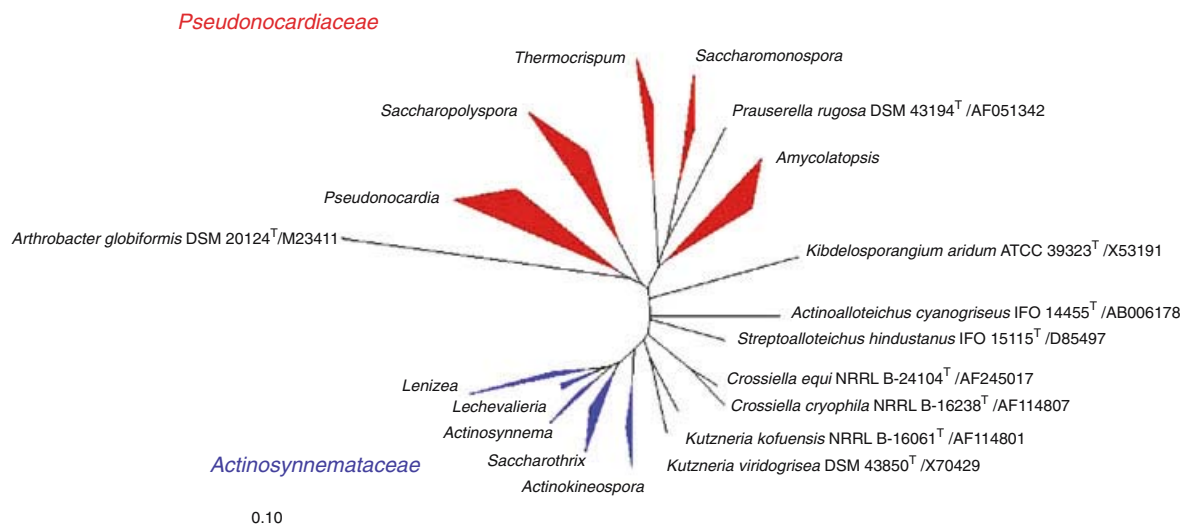

Fig. 1. Radial phylogenetic tree of the suborder Pseudonocardinae calculated from 16S rDNA sequences using Kimura's evolutionary distance methods (Kimura et al., 1980) and the neighbor-joining method of Saitou and Nei (1987). This tree illustrates the relationship of the family Actinosynnemataceae to the family Pseudonocardiaceae.

were observed to have unique morphological properties. Strains of this genus were observed to produce synnemata or dome-like bodies on most media, and the aerial mycelia produced on the synnemata eventually fragment into peritrichously flagellated motile zoospores in aqueous environments. The genus currently contains *Actinosynnema mirum*, the type species, and *Actinosynnema pretiosum* and its subspecies *Actinosynnema pretiosum* subsp. *auranticum* (Hasegawa et al., 1983). All of the species of this genus formally described to date have been isolated from the surface of blades of grass.

The genus *Lechevalieria* was recently described by Labeda et al. (2001) and contains *Lechevalieria aerocolonigenes* and *Lechevalieria flava*; both species were transferred from *Saccharothrix aerocolonigenes* and *Saccharothrix flava*, respectively, when they were shown to be phylogenetically distinct from either *Saccharothrix* or *Lentzea* and exhibited chemotaxonomic differences from these genera.

The genus *Lentzea* was first described (Yassin et al., 1995) on the basis of a single strain obtained from a tissue specimen from the abdominal cavity of a patient with peritoneal carcinoma. Phylogenetic analysis based on 16S rDNA sequences indicated that this isolate was related to *Actinosynnema* and *Saccharothrix*, which have similar chemotaxonomic characteristics. The pathogenicity of this species was never confirmed, particularly since the description is based on only one isolate. Recently, Lee et al. (2000) proposed that the type species *Lentzea albidocapillata* be transferred to the genus *Saccharothrix* as *Saccharothrix albidocapillata*,

effectively abolishing this genus. A subsequent phylogenetic study (Labeda et al., 2001) reported phylogenetic and chemotaxonomic evidence that supported the revival of this genus and addition of the new species *Lentzea californiensis* and *Lentzea albida*, which had been proposed as the taxon "*Asiosporangium albidum*" (Itoh et al., 1987; Runmao et al., 1995; Tamura and Hatano, 1998). The transfer of *Saccharothrix violacea* and *Saccharothrix waywayandensis* to the genus *Lentzea* as *Lentzea violacea* and *Lentzea waywayandensis*, respectively, added two more species.

The genus *Saccharothrix* was described by Labeda et al. (1984) to contain nocardioform actinomycetes that morphologically resembled *Nocardiopsis* in the ability of their aerial and substrate mycelia to fragment into ovoid, non-motile elements. *Saccharothrix* strains contain the *meso*-isomer of diaminopimelic acid in their cell walls, but are chemotaxonomically distinct from *Nocardiopsis* by containing rhamnose in addition to galactose as a diagnostic whole cell sugar. When first described, the genus consisted of only one species, *Saccharothrix australiensis*, but currently it consists of four species representing strains originally isolated from nature, i.e., *Saccharothrix australiensis*, *Saccharothrix espanaensis* (Labeda and Lechevalier, 1989), *Saccharothrix texasensis* (Labeda and Lechevalier, 1989b) and *Saccharothrix tangerinus* (Kinoshita et al., 1999), as well as 7 species and subspecies transferred from other genera, i.e., *Saccharothrix mutabilis* subsp. *capreolus* (Grund and Kropentstedt, 1989), transferred from the genus *Nocardia*; and *Saccharothrix mutabilis* subsp.

mutabilis (Grund and Kroppentstedt, 1989; Labeda and Lechevalier, 1989), *Saccharothrix coeruleofusca* (Grund and Kroppentstedt, 1989), *Saccharothrix coeruleoviolacea* (Grund and Kroppentstedt, 1989), *Saccharothrix longispora* (Grund and Kroppentstedt, 1989) and *Saccharothrix syringiae* (Grund and Kroppentstedt, 1989), transferred from the genus *Nocardiopsis*.

Habitats of Each Genus

Actinokineospora

Strains of the species of *Actinokineospora* have been isolated from plant material or directly from soil. More specifically, *Actinokineospora riparia* and *Actinokineospora terrae* have been isolated from soil samples taken in the proximity of a pond (Hasegawa, 1988; Tamura et al., 1995), strains of *Actinokineospora inagensis* and *Actinokineospora diospyrosa* from fallen leaves (Tamura et al., 1995), and strains of *Actinokineospora globicatena* from both soil samples and fallen leaves collected adjacent to the shores of lakes and ponds (Tamura et al., 1995).

Actinosynnema

The strains of the described species of *Actinosynnema* have all been isolated directly from plant material, primarily the surfaces of blades of grass (Hasegawa, 1978) and sedge (*Carex* species; Hasegawa et al., 1983). Hayakawa et al. (2000) recently reported the use of a new technique that permits the isolation of *Actinosynnema* strains from several different soil samples.

Lechevalieria

The genus *Lechevalieria*, at present, consists of *Lechevalieria aerocolonigenes* and *Lechevalieria flava*, originally isolated from soil samples obtained in Japan and Russia, respectively.

Lentzea

The first described strain of *Lentzea*, the type species *Lentzea albidocapillata*, was isolated from a tissue sample from the peritoneal cavity of a cancer patient (Yassin et al., 1995), but species subsequently added to this genus are from soil samples obtained in China, Korea, and the United States, suggesting that the distribution of genus members in soils is probably global.

Saccharothrix

The original strain of *Saccharothrix australiensis*, the type species of the genus, was isolated from

a soil sample from Australia. The genus appears to be ubiquitous in soils and has a worldwide distribution. Isolates described as members of this genus have come from soil samples collected in the United States, Japan, Panama, Africa, and Russia.

Isolation and Cultivation

Strains of *Actinokineospora* have been routinely isolated on humic acid-vitamin agar (HV agar; Hayakawa and Nonomura, 1987), using a modification of the procedure of Makkar and Cross (1982). Soil or leaf litter samples are air dried at 28°C for 7 days, 0.5 g of sample is mixed with 50 ml of sterile tap water, and then the mixture is incubated at 20°C for 55 minutes with occasional shaking. Aliquots (0.1 ml) of dilutions of the supernatant are spread on the surface of plates and incubated at 28°C for 2–3 weeks.

Hayakawa et al. (2000) recently described a new technique for the isolation of actinomycetes having motile zoospores. In this technique, a 0.5 g sample of air-dried soil or leaf litter is placed in a conical beaker (46 mm × 60 mm) and gently flooded with 50 ml of sterile 10 mM phosphate buffer (pH 7.0) containing 10% soil extract. The vessel is loosely covered and incubated statically at 30°C for 90 minutes to permit liberation of motile zoospores. An 8-ml aliquot of the supernatant is transferred to a 16.5 × 105 mm screw cap tube and centrifuged for 20 minutes at 1,500 g at room temperature. The tube contents are allowed to settle for 30 minutes, a portion of the supernatant is diluted serially with sterile tap water, and 0.2 ml aliquots are spread onto the surface of HV medium (containing cycloheximide [50 µg/ml]) with and without the addition of trimethoprim (20 µg/ml) and nalidixic acid (10 µg/ml). The plates are incubated for 2–3 weeks at 30°C and are then observed with a microscope fitted with a high-dry long working distance objective for the tentative identification of putative *Actinokineospora* based on morphological criteria.

Humic Acid-Vitamin (HV) Agar (Hayakawa and Nonomura, 1987)

Humic acid	1.0 g
Na ₂ HPO ₄	0.5 g
KCl	1.7 g
MgSO ₄ · 7H ₂ O	50 mg
FeSO ₄ · 7H ₂ O	10 mg
CaCO ₃	10 mg
Agar	15.0 g

Before it is added to the medium, the humic acid is dissolved in 10 ml of 0.2 N NaOH. The medium components are dissolved in 1 liter of distilled water, and the medium is adjusted to pH 7.2, then autoclaved, and finally amended with 1 ml of the filter-sterilized vitamin stock solution after tempering.

Vitamin Stock Solution

Thiamine hydrochloride	0.5 mg
Riboflavin	0.5 mg
Niacin	0.5 mg
Pyridoxine hydrochloride	0.5 mg
Inositol	0.5 mg
Calcium pantothenate	0.5 mg
<i>p</i> -Aminobenzoic acid	0.5 mg
Biotin	0.25 mg

These vitamins (per ml) are dissolved in distilled water and the solution is filter sterilized.

Strains of the genus *Actinosynnema* have been isolated from grass blades placed on yeast extract agar (0.02% yeast extract and 1.5% agar in distilled water). It has been reported that *Actinosynnema mirum* is not inhibited by the presence of nystatin at 100 µg/ml and candicidin at 50 µg/ml, so it might be possible to use these antibiotics to suppress the growth of fungal competitors. The plates containing the grass blades are incubated for 3 weeks at 28°C, after which the agar surface may be covered with various types of growth, but small synnemata can be observed on the grass blade itself using a stereoscopic microscope. These synnemata can be carefully picked off using a sterile loop and transferred to fresh media. The technique of Hayakawa et al. (2000) described above for *Actinokineospora* has also been reported to permit the isolation of *Actinosynnema* strains from soils and plant material.

Strains of *Lechevalieria*, *Lentzea* and *Saccharothrix* have been isolated from soil samples by spreading serial soil dilutions onto the surface of routine selective media (such as 1.5% crude agar and 0.4% casein hydrolysate in tap water) used for the general isolation of actinomycetes. The use of antibiotics to selectively isolate members of this group has also been reported (Shearer, 1987).

Typical actinomycete isolation media, such as AV (arginine-vitamin) agar or starch-casein agar, amended with a combination of penicillin G (5–10 µg/ml) and nalidixic acid (15 µg/ml), have been used to isolate *Saccharothrix* strains selectively (Shearer, 1987).

AV Agar (Nonomura and Ohara, 1969)

L-Arginine	0.3 g
Glucose	1.0 g
Glycerol	1.0 g
K ₂ HPO ₄	0.3 g
MgSO ₄ · 7H ₂ O	0.2 g
NaCl	0.3 g
Fe ₂ (SO ₄) ₃	10 mg
CuSO ₄ · 5H ₂ O	1.0 mg
MnSO ₄ · H ₂ O	1.0 mg
ZnSO ₄ · 7H ₂ O	1.0 mg
Agar	15 g

The pH of the medium is adjusted to 6.4 prior to autoclaving. A vitamin stock solution (1 ml; for composition, see above) is added to each liter of sterilized, tempered medium just prior to dispensing.

Starch-Casein Agar (Kuster and Williams, 1964)

Soluble starch	10.0 g
KNO ₃	2.0 g
Casein (vitamin-free)	0.3 g
K ₂ HPO ₄	2.0 g
MgSO ₄ · 7H ₂ O	50 mg
NaCl	2.0 g
FeSO ₄ · 7H ₂ O	10 mg
CaCO ₃	20 mg
Agar	18.0 g

The pH of this medium is adjusted to 7.0 to 7.2 prior to autoclaving.

More recently Lee et al. (2000) reported the use of tap water agar and oligotrophic medium (M5) for the isolation of *Lentzea* strains from serial dilutions of soils from a gold mine in Korea.

Oligotrophic Medium M5 (Lee et al., 2000)

Glucose	0.1 g
K ₂ HPO ₄	0.5 g
NaH ₂ PO ₄	0.7 g
KNO ₃	0.1 g
MgSO ₄ · 7H ₂ O	0.1 g
NaCl	0.3 g
CaCl ₂ · H ₂ O	20 mg
FeSO ₄ · 7H ₂ O	200 mg
CuSO ₄ · 5H ₂ O	90 µg
MnSO ₄ · 4H ₂ O	20 µg
ZnSO ₄ · 7H ₂ O	180 µg
CoSO ₄ · 7H ₂ O	10 µg
(NH ₄) ₆ Mo ₇ O ₂₄ · 4H ₂ O	5 µg
H ₃ BO ₃	200 µg
Agar	15 g

The ingredients are dissolved in one liter of tap water, adjusted to pH 7.2 and autoclaved.

Cultivation

Strains of the family Actinosynnemataceae are rather nonfastidious in their growth requirements and can be cultivated on a range of standard media typically used for actinomycetes, such as media described by Pridham et al. (1957) or used by the International *Streptomyces* Project (Shirling and Gottlieb, 1966): inorganic salts-starch agar, yeast extract-malt extract agar, or glycerol-asparagine agar. Two excellent media for the routine cultivation of strains are N-Z amine with soluble starch and glucose medium (ATCC Medium No. 172; Cote et al., 1984) and Bennett's Agar (ATCC Medium No. 174; Cote et al., 1984).

N-Z Amine with Soluble Starch and Glucose (ATCC Medium No. 172)

Glucose	10.0 g
Soluble starch	20.0 g
Yeast extract	5.0 g
N-Z amine type A	5.0 g
CaCO ₃	1.0 g
Agar	15.0 g
Distilled water	1.0 liter

Adjust pH to 7.3 prior to autoclaving. A good substitute for N-Z amine type A is enzymatic hydrolyzate of casein (cat. no. C0626; Sigma Chemical Company, St. Louis, Missouri, USA).

Bennett's Medium (ATCC Medium No. 174)

Yeast extract	1.0 g
Beef extract	1.0 g
N-Z amine type A	2.0 g
Glucose	10.0 g
Agar	15.0 g
Distilled water	1.0 liter

Adjust pH to 7.3 prior to autoclaving. A good substitute for N-Z amine type A is enzymatic hydrolyzate of casein (cat. no. C0626; Sigma Chemical Company, St. Louis, Missouri, USA).

Preservation of Cultures

Members of the family Actinosynnemataceae can generally be preserved as mycelia/spore suspensions or colony plugs prepared from young plate cultures (7–14 days). Mycelia/spores harvested from liquid grown cultures or agar plugs are suspended in sterile 20% (vol/vol) aqueous glycerol and stored at -40°C or colder. The viability of strains frozen in this manner is quite good for considerable periods of time, but for long-term archival storage, these preparations should be stored in vapor phase liquid nitrogen or the strains lyophilized using standard procedures and stored at 4°C .

Identification Procedures

Morphology, as is typical for actinomycetes in general, plays an important role in the identification of the taxa classified within the family Actinosynnemataceae, particularly those forming distinctive sporulation structures, such as *Actinosynnema* and *Actinokineospora*. The micromorphological properties of the other genera within the family (i.e., *Lechevalieria*, *Lentzea* and *Saccharothrix*) are quite similar and thus are not as useful for generic differentiation. The morphology observed may vary with medium composition, and specific media may be required to encourage the formation of sporulation structures. Media used successfully to culture strains for this purpose are HV agar (Hayakawa and

Nonomura, 1987), tyrosine agar (Shirling and Gottlieb, 1966), and 1.5% agar in tap water. The micromorphology of colonies growing on agar plates can be observed using a long working distance objective (30–40X) and a standard binocular microscope. Agar blocks containing sporulating colonies can also be cut from agar plates, fixed with osmium tetroxide vapor, critical point dried, and mounted on a stub for coating and observation in a scanning electron microscope.

Chemotaxonomic markers have generally been found to be extremely stable and useful features for the classification of actinomycete genera and are likewise useful when applied to the identification of members of the family Actinosynnemataceae. All of the genera within the family share some common properties, such as *meso*-diaminopimelic as the diamino acid in the peptidoglycan of the cell wall, a whole cell sugar pattern containing galactose, a phospholipid pattern including a significant amount of phosphatidylethanolamine, and menaquinones having nine isoprenoid units. Other chemotaxonomic characteristics used to differentiate the genera of the family Actinosynnemataceae are shown in Table 1.

The chemotaxonomic properties of strains can be determined following the detailed procedures outlined by Lechevalier and Lechevalier (1970, 1980) and the thin-layer chromatography procedures suggested by Stanek and Roberts (1974) and Meyertons et al. (1988) for isomers of diaminopimelic acid and whole-cell sugars, respectively. Sugar content within hydrolyzates has also been determined by gas chromatography of alditol acetate derivatives (Englyst and Cummings, 1984; Saddler et al., 1991) and using high performance liquid chromatography (Tamura et al., 1994). Phospholipid content can be determined by the protocol outlined by Minnikin et al. (1984). Menaquinone analyses can be performed using the procedures outlined by Collins et al. (1977), Kroppenstedt (1982), and Tamaoka et al. (1983), and fatty acid profiles can be determined by the method of Kroppenstedt (1985).

Physiological characterization is extremely important in distinguishing between the species within each genus, and it is best evaluated using the methods described by Gordon et al. (1974), Kurup and Schmitt (1973), and Goodfellow (1971).

DNA-DNA hybridization still serves as the definitive means of determining species relatedness in bacteria. Several methods have been used to determine DNA relatedness in the family Actinosynnemataceae. DNA relatedness among species of *Lechevalieria*, *Lentzea* and *Saccharothrix* (as shown in Table 2) has been determined from $C_{ot_{0.5}}$ values (C_{ot} is the initial DNA concen-

tration [C₀] times time [t] and $C_{0t_{1/2}} = C_0 t$ at which 1/2 of the DNA has reannealed) for renaturation in 5X standard saline citrate (SSC; 1X SSC is 0.15 M NaCl and 0.015 M trisodium citrate) and 20% dimethylsulfoxide at T_m – 25°C (e.g., 66°C) using the method of Seidler and Mandel (1971) and Seidler et al. (1975) as modified by Kurtzman et al. (1980). More recent studies of DNA relatedness among the species of *Actinokineospora* have been performed fluorometrically using biotinylated DNA by the method of Ezaki et al. (1989).

Identification of Individual Genera

Actinokineospora

The cultural characteristics of all *Actinokineospora* species are rather similar: yellow to orange colonies with no visible aerial mycelia. Observation of mature cultures grown on an appropriate medium, such as HV agar or tyrosine agar, reveals the presence of short aerial hyphae that fragment into chains of spores (Figs. 2 and 3). These arthrospores are rod shaped and

Fig. 2. Light micrograph of *Actinokineospora riparia*. Photograph graciously provided by Dr. Kazunori Hatano, Institute for Fermentation, Osaka. It is from the Atlas of Actinomycetes and is used with the permission of the editor, Shinji Miyadoh, on behalf of the Society for Actinomycetes, Japan.

become actively motile when suspended in sterile water.

Actinokineospora strains have galactose as the predominant sugar present in whole cell hydrolyzates, but smaller quantities of rhamnose, mannose and arabinose are also observed. Phosphatidylethanolamine and phosphatidylethanolamine containing 2-hydroxy-fatty acids were observed as the diagnostic phospholipids. The major menaquinone found to be present was MK-9(H₄).

The described species of *Actinokineospora* can be distinguished from each other on the basis of differential physiological properties as shown in Table 3.

Actinosynnema

The cultural characteristics of *Actinosynnema* strains differ between the described species and subspecies, with *A. mirum* producing a pale yellow

Fig. 3. Scanning electron micrograph of 21-day growth of *Actinokineospora riparia*.

low to yellowish brown substrate mycelium on most media, with or without white to yellowish white sparse aerial mycelia. *Actinosynnema pretiosum* subsp. *pretiosum* produces yellow to pale orange-yellow substrate mycelia, while *A. pretiosum* subsp. *auranticum* produces distinctively yellow to orange substrate mycelia. A sparse white to yellowish-white aerial mycelium, where produced, is observed for all species. The most striking diagnostic characteristic of members of the genus *Actinosynnema* is the production of synnemata (also called “coremia”), or compacted groups of erect hyphae originating from the substrate mycelium which give rise to chains of conidia (Fig. 4). These synnemata can be large (50–200 $\mu\text{m} \times 200\text{--}1,500 \mu\text{m}$), and the chains of conidia on these synnemata give rise to peritrichously flagellated rod-shaped to ellipsoidal spores which are motile for about 30 minutes after being introduced into a liquid medium (Fig. 5). Synnemata appear to form in greatest numbers on water agar, tyrosine agar, Bennett’s agar, yeast dextrose agar, and TPC agar (Higgins et al., 1967).

Thin Potato-Carrot (TPC) Agar (Higgins et al., 1967)

Potatoes	30.0 g
Carrots	2.5 g

Boil potatoes and carrots in 1 liter of distilled water, filter, and make up to 1 liter with distilled water. Add 15 grams of agar per liter and autoclave.

Actinosynnema strains have galactose as the predominant whole cell sugar, but also contain mannose. The phospholipid content observed includes phosphatidylethanolamine, phosphatidylethanolamine containing 2-hydroxy-fatty acids, phosphatidylinositol, phosphatidylinositol mannosides, and diphosphatidylglycerol. The predominant menaquinones observed are MK-9(H₄) and MK-9(H₆).

Saccharothrix

All strains of *Saccharothrix* are quite similar in morphological appearance. Both substrate and aerial hyphae are approximately 0.5–0.7 µm in diameter and fragment into ovoid bacillary units typical of nocardioform actinomycetes (Fig. 6). The color of the substrate mycelium of *Saccharothrix* species ranges from yellow to yellowish-brown, and that of the aerial mycelium tends to be white to yellowish-white or gray, except for *S. coerulescens* and *S. longispora*, which produce blue aerial mycelia on glycerol-nitrate agar. *Saccharothrix mutabilis* is photochromogenic and tends to produce orange-yellow aerial mycelia on many media when cultivated in the light,

while the aerial mycelia are white when cultured in the dark. Soluble pigments are produced by very few species (e.g., *S. australiensis* and *S. syringae*). Aerial hyphae often display the “zig-zag” morphology, which is also typical of the genus *Nocardiopsis* (Fig. 7), thus making the differentiation between these genera rather difficult based on morphological criteria. Aerial mycelium is best observed on minimal media such as 1.5% crude agar in tap water or Czapek’s agar (Pridham and Lyons, 1980).

Fig. 7. Scanning electron micrograph of aerial hyphae of a 14-day culture of *Saccharothrix australiensis* on ATCC Medium No. 172. The aerial mycelium has fragmented into ovoid arthrospores and demonstrates typical “zig-zag” morphology. Bar = 1 μ m.

Saccharothrix strains have galactose as the predominant sugar in their whole cell sugar pattern, but also contain rhamnose and a trace of mannose. The predominant phospholipids are phosphatidylethanolamine, phosphatidylethanolamine containing 2-hydroxy fatty acids, phosphatidylinositol and phosphatidylinositol mannoside, and diphosphatidylglycerol. Glucosamine-containing phospholipids of unknown composition have been observed in *Saccharothrix mutabilis* subsp. *mutabilis* and *Saccharothrix espanaensis*. The major menaquinone observed in all species is MK-9(H₄), but MK-10(H₄) is observed in *Saccharothrix australiensis*, *Saccharothrix coeruleofusca* and *Saccharothrix tangerinus*, while MK-9(H₂) is observed in *Saccharothrix longispora*.

Diagnostic nucleotide signature patterns in the 16S rDNA gene sequence, CACG (607–610), GTGG (617–620) and GTC (843–845), are extremely useful for differentiating *Saccharothrix* species from *Lentzea* and *Lechevalieria* (Fig. 8). *Saccharothrix tangerinus* is the most

Fig. 8. Signatures in 16S rDNA sequence for genera in the family Actinosynnemataceae.

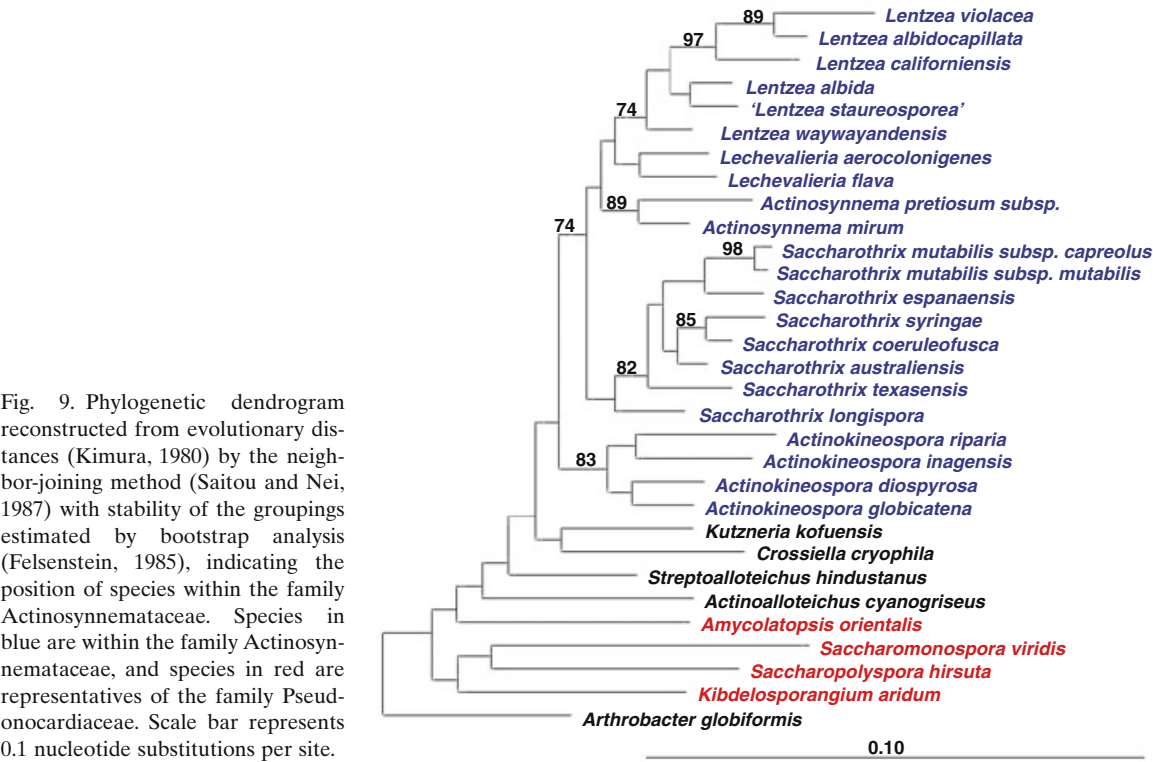

Fig. 9. Phylogenetic dendrogram reconstructed from evolutionary distances (Kimura, 1980) by the neighbor-joining method (Saitou and Nei, 1987) with stability of the groupings estimated by bootstrap analysis (Felsenstein, 1985), indicating the position of species within the family Actinosynnemataceae. Species in blue are within the family Actinosynnemataceae, and species in red are representatives of the family Pseudonocardiaceae. Scale bar represents 0.1 nucleotide substitutions per site.

recently described and validated species of the genus and has the appropriate chemotaxonomic properties. In the phylogenetic tree shown in Fig. 9, this species appears to be the most phylogenetically distinct member of the genus, and the signature patterns within the 16S rDNA gene are slightly different than those of “authentic” *Saccharothrix*. Additional sequence determination will be necessary to establish whether the published sequences are real or in error.

The described species of *Saccharothrix* can be best distinguished from each other on the basis of differential physiological properties as shown in Table 5.

Lentzea

Lentzea strains are quite similar in gross morphology to members of the genera *Saccharothrix* and *Lechevalieria*, producing aerial mycelium, sometimes exhibiting “zig-zag” morphology, and fragmenting into rod-shaped elements. The members of this genus are observed to lack phosphatidylethanolamine containing 2-hydroxy-fatty acids, although they contain phosphatidylinositol and diphosphatidylglycerol, which differentiates them from *Saccharothrix*. They also appear to have galactose, mannose and small quantities of ribose, but no rhamnose in

Table 5. Differential properties of *Saccharothrix* species.

Data from Lee et al. (2000).

their whole cell sugar profiles, which differentiates them from the genera *Saccharothrix* and *Lechevalieria*.

Lentzea species can also be differentiated from *Saccharothrix* and *Lechevalieria* species by virtue of the genus diagnostic nucleotide signature TCCA (617–620) and GCC (843–845) regions in their 16S rDNA gene sequence, as can be seen in Fig. 8.

The substrate mycelium is yellow to yellow-brown in *Lentzea albidocapillata* and *Lentzea californiensis*, yellowish-orange in *Lentzea albida*, violet in *Lentzea violacea*, and pale to dark yellow in *Lentzea waywayandensis*. White aerial mycelium is produced by all species. A reddish-brown soluble pigment is produced on some media by *Lentzea violacea*, while *Lentzea californiensis* produces orange soluble pigments, particularly on Czapek's agar.

The described species of *Lentzea* can be distinguished from each other on the basis of colonial morphology and the differential physiological characteristics shown in Table 6.

Lechevalieria

The species within the genus *Lechevalieria* have had a checkered taxonomic history, with both species having spent some time in at least

four different genera, including *Saccharothrix*. *Lechevalieria aerocolonigenes* was originally described as *Streptomyces aerocolonigenes*, while *Lechevalieria flava* was originally described as *Actinomadura flava*. The members of this genus have morphology quite similar to that of *Saccharothrix* and *Lentzea*, i.e., branching vegetative mycelium and rudimentary aerial mycelium that fragments into coccoidal elements. The whole cell sugar pattern consists of galactose and mannose, with traces of rhamnose. The phospholipid pattern consists of significant quantities of phosphatidylethanolamine lacking hydroxylated fatty acids. The sequence of the 16rRNA gene contains genus-specific diagnostic nucleotide signature patterns of TT (844–845) and GGT (1107–1109; Fig. 8).

Both species of *Lechevalieria* exhibit similar gross morphology when growing in culture, with substrate mycelium of yellow shades and only traces of white aerial mycelia, and can be best distinguished through the use of the differential physiological characteristics shown in Table 7.

Applications

New strains of genera within the family Actinosynnemataceae isolated from nature in the

The Families Frankiaceae, Geodermatophilaceae, Acidothermaceae and Sporichthyaceae

PHILIPPE NORMAND

Introduction

The four families, Frankiaceae, Geodermatophilaceae, Acidothermaceae and Sporichthyaceae, embrace bacteria that have been poorly studied for several years, mostly owing to their slow growth rate and fastidious growth requirements. Apart from this common trait, the four families have little in common, which is why they had been considered unrelated until a new hierarchic classification system was proposed (Stackebrandt et al., 1997). These families, together with Microsphaeraceae, are today placed in the suborder Frankineae. The best known of these, the family Frankiaceae, comprises nitrogen-fixing bacteria that infect the roots of a number of woody dicotyledonous plants and induce the synthesis of nodules, studied for many years since their description 135 years ago (Woronin, 1866). The first confirmed isolation in pure culture of a *Frankia* strain was reported only in 1978 (Callaham et al., 1978) despite almost a century of unsuccessful efforts. The other bacteria were isolated from various environments such as soil (Geodermatophilaceae), thermal springs (Acidothermaceae), or compost (Sporichthyaceae). *Geodermatophilus* was grouped together with *Dermatophilus* in the family Dermatophilaceae until 16S rDNA studies revealed their phylogenetic unrelatedness (Stackebrandt et al., 1983). Only *Geodermatophilus* was considered morphologically related enough to be grouped together with *Frankia* in the family Frankiaceae. It was only later, with the advent of molecular techniques, that all these families were determined to be relatives of *Frankia*.

Phylogeny

The first phylogenetic study made on members of these four families was based partly on 16S reverse sequencing and mostly on 16S rRNA oligonucleotides sequencing (Hahn et al., 1989). The main conclusion of this work was that

Geodermatophilus (Luedemann, 1968) and *Blastococcus* isolated from the Baltic Sea (Ahrens and Moll, 1970) were close relatives of *Frankia*, but the study also confirmed earlier work that showed the genus *Dermatophilus* formed a separate lineage, even though this genus shared a rare morphological feature (i.e., having hyphae dividing in more than one plane to produce multilocular sporangia).

From then on, several (more than 310 in April 2002) 16S rRNA genes have been deposited in sequence databanks and a comprehensive phylogenetic study was made (Normand et al., 1996), showing strains in genus *Frankia* could be grouped into four clusters (Fig. 1) that correspond roughly to host specificities: cluster 1 comprises strains infective on *Alnus* and also strains infective on *Casuarina*; cluster 2 comprises strains not cultivated in pure culture but present in the root nodules of members of plant families Rosaceae, Datisceae, and Coriariaceae; cluster 3 comprises strains infective on Eleagnaceae and *Gymnostoma*; and cluster 4 comprises a number of diverse strains isolated from different host plants but unable to fulfill Koch's postulates and also a few strains that infect *Alnus* but not efficiently (Fig. 1). The largest distance in the 16S rRNA gene between any two *Frankia* strains was around 4% (Normand et al., 1996).

As expected, given the unusual ecological niche and the particular morphological features, all *Frankia* strains formed a coherent cluster with *Geodermatophilus* and *Blastococcus*, which are close phylogenetic neighbors. Surprisingly, *Frankia* had even closer relatives sharing hardly any morphological features with it: *Sporichthya polymorpha* isolated from compost (Rainey et al., 1993b) and *Acidothermus cellulolyticus* isolated from hot springs (Rainey and Stackebrandt, 1993a). The distances between *Geodermatophilus* and the different *Frankia* 16S rRNA sequences are 5.3–7.2%, while the distances between *Acidothermus* and the *Frankia* sequences are 4.8–6.5% (Normand et al., 1996).

These findings were found sufficiently surprising to warrant a new study. The strains were

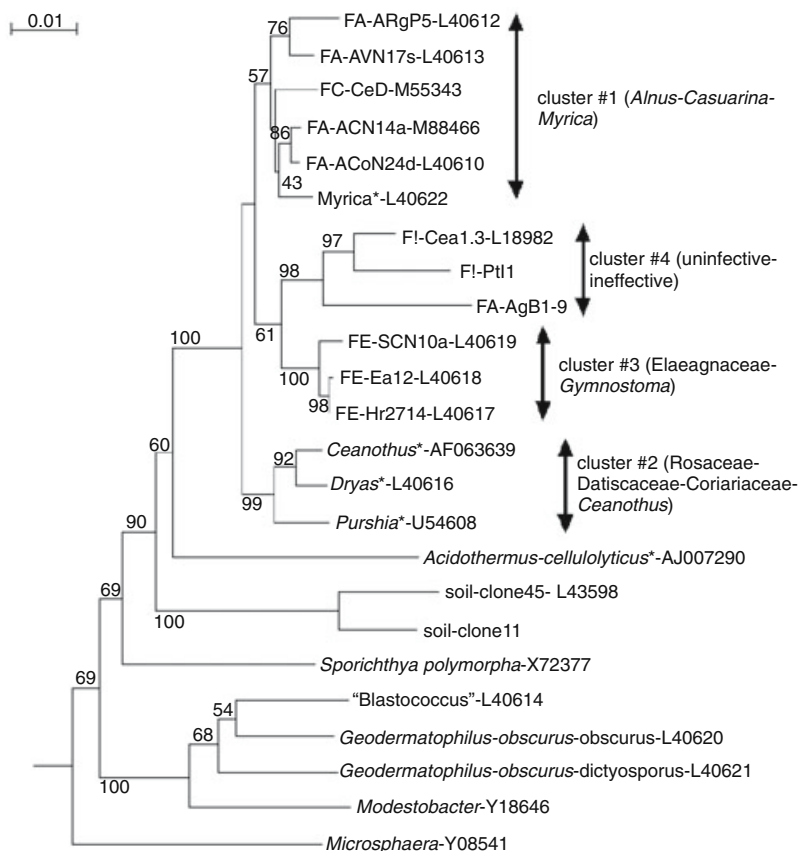

Fig. 1. Neighbor-joining (NJ) phylogenetic tree (Saitou and Nei, 1987) of the 16S rRNA gene of representative isolates belonging to the four families: Frankiaceae, Acidothermaceae, Geodermatophilaceae and Sporichthyaceae. In the *Frankia* isolates, FA refers to strains infective on *Alnus*, FE to those infective on *Eleagnus*, FC to those infective on *Casuarina*, FI to uninfective strains, and the asterisk to unisolated amplicates from plant tissues. *Kineococcus* (AB007420) was used as outgroup. The numbers beside the clusters are those previously given by Normand et al. (1996). Bootstrap replicates (Felsenstein, 1985) above 50% are indicated above the nodes. Bar represents 0.01 substitution/site.

reordered from the American Type Culture Collection (ATCC), their 16S rRNA sequenced, and their *recA* genes also studied. Several errors in the 16S rRNA gene were corrected that did not modify the phylogenetic topology, but *Acidothermus* was indeed found to be closer to *Frankia* than to *Geodermatophilus* (Maréchal et al., 2000). Besides, the *recA* gene was found to confirm the 16S rRNA gene-derived phylogeny showing close proximity of *Acidothermus* to *Frankia* (Fig. 2).

Other genes have been used to study the phylogenetic relations of *Frankia* strains, such as the *nif* genes coding for nitrogenase (Navarro et al., 1997), and the proximity of the *Gymnostoma*-infective strains to cluster 3 was thereby shown; however, these genes are absent in phyletic neighbors and also in several *Frankia* strains of cluster 4. This is also the case for *glnII* that codes for the assimilatory glutamine synthetase (Cournoyer and Lavire, 1999), but its use has remained modest despite its phylogenetic potential.

Some anomalies in phylogenetic groupings were noted when 16S rDNA trees based upon partial and complete genes were compared. These anomalies concerned mainly the strains infective on *Casuarina* (cluster 1). When partial

16S rRNA sequences are used (lacking 300 nucleotides from the 5' end), these *Casuarina*-infective *Frankia* are separated from the *Alnus*-infective *Frankia* and group close to cluster 2 (Huguët et al., 2001). This topology with the *Casuarina*-infective *Frankia* close to the *Alnus*-infective *Frankia* appears to be consistent with conclusions drawn from studies of morphology and the sequence of the 23S rRNA insertion (Hönerlage et al., 1994).

Given that the bona fide *Frankia* strains form a coherent phylogenetic cluster relative to its neighbors, a *Frankia*-specific 16S rDNA primer was identified and tested. Only one region in the 5' part of the gene was found appropriate and was used in combination with a universal primer at the 3' part of the gene. All *Frankia* strains tested yielded positive amplicons with pure culture DNA, while DNA from non-*Frankia* strains was not amplified. Consequently, the primer pair was used to follow *Frankia* in soil, along a chronosequence of soil colonization by *Alnus* in the Alps. Several positive amplicons, two of which originated from the *Alnus* rhizosphere, were obtained and found to belong to undescribed close relatives of *Frankia* with about 5% distances in the 16S rRNA gene (Normand and Chapelon, 1997). This finding emphasized the

Fig. 2. Neighbor-joining (NJ) phylogenetic tree (Saitou and Nei, 1987) of the *rbcL* gene of representative actinorhizal species belonging to the eight families: Betulaceae, Casuarinaceae, Myricaceae, Rosaceae, Elaeagnaceae, Rhamnaceae, Coriariaceae and Datisaceae. *Pinus pinea* (AB019822) was used as outgroup. The numbers beside the family abbreviations refer to the cluster (Fig. 1) to which the majority (large characters) or a minority (small characters) of *Frankia* strains belong. Bootstrap replicates (Felsenstein, 1985) above 50% are indicated above the nodes. Bar represents 0.01 substitution/site.

previous notion that the group of actinomycetes described here contains slow growers and may remain poorly defined until an appropriate screening strategy has been developed.

Some isolates are listed in Genbank as *Frankia* strains although a phylogenetic analysis shows that they do not belong to the cluster. This is true of strains G48 (accession number L11306) and L27 (M59075) described as *Frankia* strains isolated from *Podocarpus*, a plant genus belonging to the Coniferales for which nodulation by *Frankia* has been claimed (Benson et al., 1996). As this claim was later dropped, there is now a general agreement among scientists working on *Frankia* that *Podocarpus* is not in symbiosis with *Frankia*. The isolates that appear to belong to the actinomycetes genus *Micromonospora* are still wrongly labeled in Genbank.

One major phylogenetic question that arises from the study of the actinorhizal symbiosis is whether the phylogenetic trees obtained from the symbionts and the host organisms are sufficiently congruent to indicate coevolution. Indeed, the congruency between the 16S rRNA gene of the bacteria and the *rbcL* gene of the host plants is relatively convincing (Jeong et al., 1999). However, under closer scrutiny, several deviations (Fig. 2) from complete congruence

are noted: 1) among the Casuarinaceae, *Gymnostoma* is indeed close to *Casuarina* yet it is nodulated by strains of cluster 3; 2) Elaeagnaceae and Rhamnaceae both belong to the Rhamnales, yet the former is nodulated by strains of cluster 3, while genus *Ceanothus* of the Rhamnaceae (Clawson et al., 1998) is nodulated by strains of cluster 2; and 3) Rosaceae that are nodulated by strains of cluster 2 are closer to the Rhamnales nodulated mainly by strains of cluster 3 than to the Coriariaceae and Datisaceae nodulated by strains of cluster 2. Finally, *Alnus* is nodulated by strains of clusters 4 and 1, while *Myrica* is nodulated by strains of clusters 3 and 1. All these inconsistencies indicate that the evolution of *Frankia* did not proceed in a linear fashion, dominated by gradual plant evolution, but rather that other factors (such as climate or soil formation) may have played a major role.

The genus *Geodermatophilus*, which was originally described for isolates obtained from desert soils, has new isolates regularly added to it. These are obtained from various environments (soil, stones, walls, etc.) and the current tally is 33 16S rDNA entries in Genbank. *Blastococcus*, which was isolated from the Baltic Sea (Ahrens and Moll, 1970) and which has very few phenotypic

features that distinguish it from *Geodermatophilus*, may eventually be reclassified as a member of *Geodermatophilus*, inasmuch as the single known strain was placed by 16S rRNA gene analysis in the middle of the *Geodermatophilus* cluster (Fig. 1). *Modestobacter multiseptatus* isolated from polar soil (Mevs et al., 2000) is positioned at the bottom of the *Geodermatophilaceae* cluster.

All these families (Frankiaceae, *Geodermatophilaceae*, *Acidothermaceae* and *Sporichthyaceae*) are listed on the National Center for Biotechnology Information (NCBI) taxonomy page as belonging to the Frankineae suborder as defined recently (Stackebrandt et al., 1997). Other families (not treated in this chapter) of this suborder are *Kineosporiaceae* (*Cryptosporangium*, *Kineococcus* and *Kineosporia*) and *Microsphaeraceae* (*Microsphaera*).

Taxonomy

The discriminatory phenotypic features of the families Frankiaceae, *Geodermatophilaceae*, *Acidothermaceae* and *Sporichthyaceae* are shown in Table 1.

Frankia strains are characterized as producing branched hyphae, multilocular sporangia and nonmotile spores. Most strains will have an optimal growth temperature of 25–30°C. Most strains will grow on nitrogen-free medium, except of course those belonging to cluster 4.

Species description of genus *Frankia* has taken a notably long period to achieve owing to the slow growth rate of many strains, and several actinorhizal plants have not yielded isolates even able to fulfill Koch's postulates (see below). The first DNA-DNA reassociations, made on a small number of isolates, resulted in the expected conclusion that isolates belonged to more than one species (An et al., 1985). Several isolates had high levels of similarity with an *Alnus*-infective strain, several with a *Casuarina*-infective strain, and none with an *Elaeagnus*-infective strain. A more comprehensive study (Fernandez et al., 1989) was done with 35 isolates. Within the group of isolates infective on *Alnus*, one genomic species dominated numerically and was named

"*Frankia alni*" by Becking (1970). Two other *Alnus*-infective genomic species emerged with four and one representatives. The group of strains infective on *Elaeagnus* comprised 5 genomic species, while the group of strains infective on *Casuarina* comprised only a single species. This is in line with the published diversity in the *nifH* restriction fragment length polymorphism (RFLP) patterns of these two groups of strains (Nazaret et al., 1989). Three other papers (Bloom et al., 1989; Akimov and Dobritsa, 1992; Lumini et al., 1996) have been published that show a profusion of genomic species defined by DNA-DNA reassociation values, but no species names have been proposed. Results of these studies agreed with the characterization of the *nif* region, done in parallel with hybridization studies.

Only one species, *Frankia alni*, was named because of the few available phenotypic characters that would circumscribe the genomic clusters identified by DNA-DNA hybridization data. This is true for both *Alnus*-infective strains and especially *Elaeagnus*-infective strains. Of these, the group of strains infective on *Casuarina* merit species status, and the strains sharing several phenotypic features (host spectrum and DNA sequence) should be named *Frankia casuarinae*. Discriminatory phenotypic features are listed below together with group-specific primers that target a hypervariable region located around position 990 in the 16S rRNA gene (Bosco et al., 1992; Table 2).

In the *Geodermatophilaceae*, species (and genera) have been named without DNA-DNA hybridization as recommended by the International Committee on Systematics of Prokaryotes. In genus *Geodermatophilus*, only one species has been named, *Geodermatophilus obscurus*, on the basis of phenotypic characterization, and it contains several subspecies (*amargosae*, *dictyosporus*, *obscurus*, and *utahensis*; Luedemann, 1968; Table 3).

Isolation

Even though nowadays several hundreds of *Frankia* isolates are available, isolation in pure

culture of *Frankia* strains remains a difficult task. The isolation varies from one host plant to the other: the easiest to work with are the Elaeagnaceae and the most difficult are the Coriariaceae, Datisceae and Rosaceae. In these three plant families and in the genera *Allocasuarina* (Casuarinaceae) and *Ceanothus* (Rhamnaceae), no isolate is able to fulfill Koch's postulates. Though some of these isolates do belong to the genus *Frankia*, they do not fix nitrogen (Mirza et al., 1994).

Several procedures for isolating *Frankia* have been published and some, especially the historic ones, were complex with mechanical and enzymatic dissection steps (Callahan et al., 1978). Subsequent protocols were much simpler. Although time consuming, the dissection step is nevertheless considered crucial to avoid isolation of "atypical" isolates present in the outer cortical layers and unable to fulfill Koch's postulates (H. G. Diem, personal communication). The addition of activated charcoal or polyvinylpyrrolidone appears to increase the probability of obtaining bacterial growth because these agents remove inhibiting plant phenolic compounds (Lechevalier and Lechevalier, 1990). Different media, both liquid and with agar, have been used successfully to obtain isolates from nodule tissues of *Alnus*, *Elaeagnus*, *Casuarina*, etc., and in one instance, directly from the soil (Baker and O'Keefe, 1984). Most strains are microaerophilic, and thus agitation of liquid medium should be avoided or a soft agar overlay used in the case of solid medium. Most isolation attempts use complex media, for instance yeast dextrose agar (Baker and Torrey, 1979) or QmodB medium that contains lecithin (Lalonde and Calvert, 1979), although use of simpler media such as tap water agar has been advocated

(Lechevalier and Lechevalier, 1990) to reduce the growth of competing microbes. This notion raises a crucial point relating to the purity of the cultures used, especially when a poor medium has been used in the first steps of isolation. Most strains presently in use have not been derived from single cells, and thus it is not surprising to still find slow-growing contaminants, even after years of study. Optimal temperature for growth is 28°C, although tropical strains (e.g., from Casuarinaceae) have a higher optimum temperature. Incubation proceeds for 3–4 weeks before putative *Frankia* isolates are checked under the microscope and subcultured.

Geodermatophilus was first isolated from desert and forest soils (Luedemann, 1968) on a dilute medium containing yeast extract 0.1%, glucose 0.1%, soluble starch 0.1%, CaCO₃ 0.1% and 1.5% agar (to prevent overgrowth of fungi and bacteria following incubation at 28°C for 2–3 weeks). After microscopic observation, colonies were subcultured on richer medium (yeast extract, 0.5%; mixture of amines, 0.5%; glucose, 1%; soluble starch, 2%; CaCO₃, 0.1%; and 1.5% agar). A recently described technique (Hayakawa et al., 2000), based on the fact that *Geodermatophilus* has zoospores that are motile by means of terminal flagella, includes a gentle centrifugation step that sediments nonmotile actinomycetes prior to plating on a medium selective for actinomycetes. A recent paper (Mevs et al., 2000) describes the isolation from Antarctic soils on an oligotrophic medium of a bacterium designated "*Modestobacter multiseptatus*, sp. nov., gen. nov.," a close relative of *Geodermatophilus*. Isolates belonging to genus *Geodermatophilus* are now regularly described from dry soils and also from rock surfaces (Eppard et al., 1996; Urzi et al., 2001).

Acidothermus cellulolyticus is available as a single strain (ATCC 43068^T), although three strains were isolated initially during the screening program aimed at exploiting the natural microbial biodiversity in Yellowstone National Park (Mohagheghi et al., 1986). To obtain microbial isolates that could efficiently convert biomass into alcohol for fuel, samples of mud and decaying wood were inoculated in liquid medium containing cellulose as sole carbon source and incubated at 55°C and pH 5.2. No other isolate has been described, even though the procedure appears straightforward and the potential benefits are important.

Isolation of *Sporichthya polymorpha* was first reported in 1968 (Lechevalier et al., 1968) from soil samples using a dilute medium (tap water or one-tenth strength Czapek agar). This organism is considered a rare actinomycete as only five isolates have been obtained over 20 years. Recently, on the basis of the fact that *Sporichthya* also has motile zoospores, the same gentle centrifugation technique followed by plating on selective medium previously used for the isolation of *Geodermatophilus* was used and found successful for *Sporichthya* (Hayakawa et al., 2000). Suzuki (1999) used the same technique together with a highly selective medium (humic acid-vitamin agar [HVA] that contains soil humic acid as the sole source of carbon and nitrogen supplemented with gellan gum and calcium chloride to stimulate formation of spores and aerial mycelium) and reported numerous isolates of *Sporichthya*.

Preservation and Cultivation

Most *Frankia* strains are microaerophilic, grow slowly, and have an optimal growth temperature in the range of 25 to 33°C (Lechevalier and Lechevalier, 1990). This is why *Frankia* strains are routinely cultivated in liquid media. For particular purposes such as germination of spores to obtain single cell isolates (Prin et al., 1991), regeneration of protoplasts (Normand et al., 1987; Tisa and Ensign, 1987), or to assess resistance to metals (Richards et al., 2002), cells are in general embedded in a soft (0.8%) agar overlay maintained at 42°C before plating. For routine purposes, several media are used, including those already described for isolation, the defined propionate medium (DPM; Baker and O'Keefe, 1984) or Biotin-Ammonium-Propionate medium (BAP; Murry et al., 1984).

The most frequent preservation method of *Frankia* strains is maintenance in rich liquid medium with infrequent (once or twice per year) subcultures. Some comprehensive lyophilization programs were dropped when reports indicated

that reculture of such lyophilized material was often problematic. Skim milk suspension that appears to contain some inhibitory compounds should be avoided, and instead, bacteria in spent medium should be used (Lechevalier and Lechevalier, 1990). CpI1, the first strain that was deposited in the American Type Culture Collection (ATCC) and seemingly kept as lyophilized material, was found not to be viable and is now absent from the list of available strains. The only strain listed as available from the ATCC is AvcI1, a cluster 1 *Alnus*-infective strain (Baker et al., 1980), available freeze-dried.

Frankia spores are not able to withstand high temperatures. The highest reported temperature (55°C) is only slightly higher than the highest temperature (52°C) tolerated by hyphae (Lalonde and Calvert, 1979). Some strains isolated from *Casuarina* produce particular hyphae called "torulose hyphae," which have thickened walls, are produced in old cultures, and can be subcultured (Diem and Dommergues, 1985). Diazo-vesicles also have the potential to differentiate into hyphae (Schultz and Benson, 1989).

Geodermatophilus is relatively easy to grow at 28°C on solid rich medium (e.g., 0.5% yeast extract, 0.5% amine mixture, 1% glucose, 2% soluble starch, 0.1% CaCO₃, and 1.5% agar; Luedemann, 1968) or on TYB (tryptone, yeast extract, glucose and NaCl at pH 7; Ishiguro and Wolfe, 1970). Carbohydrate utilization in *Geodermatophilus* isolates is in general broad: L-arabinose, D-galactose, D-glucose, D-levulose, D-mannitol, sucrose and D-xylose (Luedemann, 1968).

Acidothermus is more tedious to work with mainly because of evaporation problems connected with its optimal growth above 55°C. Good growth occurs in low phosphate basal salts medium (Mohagheghi et al., 1986) containing yeast extract and cellulose. Different optimum temperatures have been reported but the average was 58°C, while the optimum pH was 5.0.

Sporichthya is grown at 26°C in standard yeast malt extract agar from Difco (Lechevalier et al., 1968).

Geodermatophilus, *Acidothermus* and *Sporichthya* are available from the ATCC in freeze-dried form.

Physiology

Nitrogen Fixation, Partial Pressure of Oxygen, and Vesicles

In contrast to most *Rhizobium* strains, nitrogen fixation has been found to occur not only in actinorhizal nodules but also in pure cultures of *Frankia* in the absence of fixed nitrogen. Growth

without fixed nitrogen, however, is much slower and is associated with the synthesis of diazovesicles (specialized cells with thickened walls that provide a barrier to the diffusion of oxygen). It was even found that nitrogen fixation, which is a reductive process inhibited by molecular oxygen, could occur at normal oxygen pressure but also at hyperbaric oxygen concentration (Harris and Silvester, 1992). Increasing partial oxygen pressure results in increased thickness of the vesicles' cell wall and the compound involved was identified as hopanoid lipids (Berry et al., 1993). Hopanoid lipids, which behave like cholesterol as membrane hardeners, are present at such high concentrations in *Zymomonas mobilis* that cells are able to grow in up to 10% ethanol and in *Alicyclobacillus acidocaldarius* that cells are able to grow in acidic thermal springs (Poralla et al., 1980). Hopanoid lipids are also present at concentrations of 15% in *Acidothermus cellulolyticus* (Maréchal et al., 2000).

In *Frankia* cells, two types of glutamine synthetases (GSs) incorporate ammonium into glutamic acid to yield glutamine (Schultz and Benson, 1990). Both GSI (heat-stable, dodecameric, constitutive, and coded by *glnA*) and GSII (heat-labile, octameric, inducible by N-starvation, and coded by *glnB*) are present in vesicles at levels similar to those detected in vegetative hyphae from N₂-fixing cultures (Rochefort and Benson, 1990). However, glutamate synthase, glutamate dehydrogenase, and alanine dehydrogenase activities, all of which are involved in subsequent steps of ammonium assimilation, are restricted to the vegetative hyphae. Thus, diazovesicles apparently lack a complete pathway for assimilating ammonia beyond the glutamine stage.

Effect of Phenolic Compounds

In actinorhizal nodules, *Frankia* growth is restricted to the central part of the thickened cortex and it has been hypothesized that the plant controls the growth of its symbiont by preventing its access to some parts of the nodule. Given that root nodules contain high amounts of tannins (which can be described as phenolic), the effect of phenolic compounds on the growth and morphology was investigated and it was found that some compounds repressed sporulation (coumaric, ferulic, and *trans*-cinnamic acids), induced vesicle formation (benzoic and hydroxybenzoic acids), or repressed growth (coumaric acid; Perradin et al., 1983).

Superoxide Dismutase

Normal aerobic metabolism produces molecular oxygen (O₂), which is toxic to cell constituents in

general and to the 4Fe-4S cluster containing enzymes in particular. Nitrogenase is one of the enzymes in the 4Fe-4S cluster and thus is particularly sensitive to oxygen radicals. Enzymes capable of metabolizing this compound, the superoxide dismutases (Sods), belong to two types: the manganese-iron Sods and the copper-zinc Sods. Given the sensitivity of nitrogenase to O₂, this enzyme has been looked for in numerous nitrogen-fixers and indeed detected in actinorhizal nodules (Alskog and Huss-Danell, 1997) and in pure cultures, where its level was among the highest reported in prokaryotes (Steele and Stowers, 1986). Using a two-dimensional (2D)-gel electrophoresis approach, the effect of plant exudates on *Frankia* in pure culture was investigated. Among the five spots overexpressed in response to *Alnus glutinosa* root exudates, one spot was found to be an iron Sod (Hammad et al., 2001).

Carbon/Nitrogen Exchange in Nodules

Frankia strains can grow on a variety of carbon sources, relatively well on small molecular weight compounds such as acetate or propionate, and also on malate, pyruvate and succinate, and particularly cluster 1 strains can grow on Tween 80. In contrast, growth on sugars is poor. Sugars are added to growth media to stimulate growth (and thus increase detection) of contaminants. ¹⁴C-labeling experiments with cluster 1 strains, by far the most studied strains, showed that propionate metabolism proceeds via active transport followed by activation with coenzyme A, carboxylation to methyl-malonyl CoA and racemization to succinyl-CoA, which then can be processed in the tricarboxylic acid cycle (Stowers et al., 1986). Glycogen and trehalose have been identified as major storage compounds in *Frankia* (Lopez et al., 1984), with their level correlated negatively with the energy-demanding nitrogen fixation activity (Fontaine et al., 1984).

Hydrogenase

In contrast to leguminous nodules, actinorhizal nodules emit little or no hydrogen, a by-product of nitrogenase activity. The presence of an uptake hydrogenase, the enzyme involved in the recycling of the energy-rich gas, has been demonstrated in nodules (Benson et al., 1980) and in pure cultures (Lindblad and Sellstedt, 1989; Murry and Lopez, 1989). The enzyme's large subunit was located in the membrane by immunogold staining (Mattsson and Sellstedt, 2000) and its activity correlated with nitrogenase activity.

Genetics

The genetics of *Frankia* in pure culture has been limited by the lack of a transformation system. Several attempts at genetic transformation using naked DNA (Cournoyer and Normand, 1992) or conjugation have failed. However, a promising breakthrough has been the conjugation between *Enterococcus* and *Frankia* by means of a conjugative plasmid (Myers et al., 2001[Abstract]).

Organization of the *nif* Cluster

The *nif* genes that code for the nitrogenase enzyme complex are among the most conserved bacterial genes. The organization of the gene cluster in *Frankia* has been determined by hybridization with the *nifHDK* genes of *Klebsiella pneumoniae* (Normand et al., 1988). The gene order in the core system (HDKENX) is conserved as in most systems analyzed so far.

Glutamine Synthetase Genes

Frankia strain CpI1 has two genes coding for glutamine synthetase (Hosted et al., 1993), the protein responsible for adding ammonia to glutamate to yield glutamine. The arrangement of genes appears to result from an early (a 300 million-year-old) gene duplication and is conserved in several bacteria (Kumada et al., 1993). This region (especially the *glnB* gene) is highly variable (Cournoyer and Lavire, 1999) and thus suitable for phylogenetic analysis of closely related strains. The *Frankia glnB* gene was capable of complementing an *E. coli glnA* mutant but only when transcribed from the lac promoter (Rocheftort and Benson, 1990).

Proteasome

The genes coding for the extracellular protease complex called the "proteasome" have been isolated and characterized from the cluster 1 *Frankia* strain ACN14a (Pouch et al., 2000). When compared to the homologous sequences in other actinobacteria (i.e., *Rhodococcus erythropolis*, *Mycobacterium tuberculosis* and *Streptomyces coelicolor*), the structure and gene order are conserved.

Sod

As explained above, the superoxide dismutase is especially important to nitrogen-fixing microorganisms. The Sod enzyme is present in two forms, the constitutive one containing Mn as ligand and the inducible one containing Fe as ligand; the

enzyme is induced by switch to nitrogen-fixing conditions (Steele and Stowers, 1986) or exposure to plant root exudates (Hammad et al., 2001). The respective gene has been isolated and found to complement *E. coli* mutants. The expression level with its own promoter was much lower than that with an *E. coli* promoter (P. Normand, in preparation), suggesting that *Frankia* promoters are not well recognized by the *E. coli* expression machinery, as was previously reported for the *glnA* gene (Rocheftort and Benson, 1990).

The *shc* Gene

This gene codes for a squalene hopene cyclase, an intermediary enzyme in the anabolic pathway from acetyl-CoA to hopanetetrol, and has been characterized from several *Frankia* strains by amplification with conserved primers (Dobritsa et al., 2001). This compound is involved in protecting nitrogenase from oxygen in thick-walled specialized diazovesicles (already described).

Plasmids

Several plasmids have been detected in various strains, essentially from the cluster 1 strains infective on *Alnus*, varying in size from 8 kb (Normand et al., 1983) to 190 kb, the largest carrying a copy of the *nif* genes (Simonet et al., 1986). Three of the smaller plasmids have been sequenced to understand why transformation in both *Frankia* and in heterologous hosts has failed repeatedly and to develop efficient vectors. The 8-kb plasmids were found to have genes resembling the classic *kor* (kill over-ride) system for repression of toxic *kil* function: *par* for partition, *rep* for replication of DNA, and a replication origin (Lavire et al., 2001). A larger 22-kb plasmid (pFQ12) present in the same strains was found to have similar functions plus some genes with similarity to transfer and mobilization determinants (John et al., 2001).

Codon Usage

Codon usage is highly skewed toward –G and –C triplets, except for the underrepresented glycine GGG. This bias, which is usual for actinomycetes, is a useful signature to confirm that *Frankia* is the source of a gene (Ligon and Nakas, 1988).

Cellulase Genes of *Acidothermus cellulolyticus*

Acidothermus cellulolyticus was isolated using the ability to grow at high temperature on cellu-

lose as sole carbon source. The cellulase gene (U33212) was isolated and characterized as encoding a family 5 thermostable β -1,4-endoglucanase (Sakon et al., 1996). The G+C content of the region is lower (62.2 mol%) than that of *Frankia* genes known so far (66 mol% for *sodF*, 67 mol% for *recA* and *gln2*, 68 mol% for the *nifHDK* region, and 71 mol% for the proteasome region), and the highest similarity was found with a gene from *Paenibacillus polymyxa* (P23548, 63% similar), suggesting a recent lateral transfer. The gene was transformed within tobacco where it was transcribed, and the protein was targeted to the chloroplasts where it accumulated to 1.35% of soluble proteins (Dai et al., 2000).

Ecology

Frankia strains are ubiquitous in soils. In several ecological survey programs, *Alnus*, *Myrica* and *Elaeagnus* have consistently been found to be profusely nodulated (Bond, 1976), except in some anoxic situations. Some *Allocasuarina* species have also been found to be sparsely nodulated, but this has been interpreted as an evolutionary trend of the plant towards a narrower spectrum of strains (Maggia and Bousquet, 1994) and eventual elimination of the symbiont in the drier parts of Australia (Simonet et al., 1999). Even soils from sites with no known actinorhizal plants cause nodule formation on test plants, suggesting that *Frankia* can thrive in the soil in the absence of host plants (Normand and Lalonde, 1982), which was demonstrated experimentally (Rossi, 1964). It has been suggested that the ability to thrive as saprophytes varies markedly between strains. In particular, some strains that sporulate profusely in plants have been suggested to have different ecological strategies (van Dijk, 1978) and in particular to be less saprophytic.

pH Effect on Distribution of Strains

Several soil parameters are expected to play a role on the survival of spores or on the saprophytic life of hyphae. These are texture, organic matter content, pH, chemicals, pO_2 , etc. However, few of these parameters have been tested. Acidity of the soil is known to be a critical factor, acting directly on the bacterial physiology and indirectly on nutrient availability. As expected, it was found that the diversity of *Frankia* strains infective on *Elaeagnus* was reduced in an acidic soil relative to a neutral soil (Jamann et al., 1992).

Effect of Soil and Host Plant on Distribution of Strains

Actinorhizal plants are known to be pioneer plants that invade recently deforested areas following volcanic eruptions, glacier melting, forest fires, landslides, or man-made processes like deposition of mine spoils, hydrodam construction, or sand dune formation. Such processes may result in unbalanced substrate for pH or chemicals acting as selective forces on strains. Thus, it is not surprising to have differences in 50% of lethal dose (LD_{50}) for a variety of heavy metals (Richards et al., 2002). In the case of *Frankia* strains infective on *Gymnostoma* spp., this was found to result in abundance, dependent on soils and the host plant species (Navarro et al., 1999). A similar conclusion was reached in the case of *Ceanothus*-infective strains, with some strains restricted to serpentine soils (Ritchie and Myrold, 1999).

Antibiotics

Differences in antibiotic resistance were noted between strains, even closely related ones (Dobritsa, 1998), even though most differences are linked to taxonomic position. Conversely, *Frankia* has been found to synthesize unusual compounds, such as a macrocycle containing imide and orthoamide functionalities (Klika et al., 2001) and benzo[a]naphthacene quinones (Rickards, 1989).

Applications

Actinorhizal plants are pioneer species that are dominant in re-vegetating areas, following natural events such as glacier retreat or volcanic eruptions. These plants can be self-reliant in nitrogen because of their symbiosis with *Frankia*, and they are also undemanding for other nutrients, in part because of the general occurrence of symbiosis with endomycorrhizal fungi (Diem, 1996). For all these reasons, actinorhizal plants have been used for several applications where it is necessary to rapidly establish a plant cover.

The Americas and Europe

Alnus viridis subsp. *crispa* has been planted on a commercial scale in Canada (Périnet et al., 1985) to stabilize dikes in the large hydroelectric facilities of Northern Quebec and for biomass production on abandoned farmland (Prégent and Camiré, 1985) and on reclaimed oil shale sites in Alberta (Gordon and Dawson, 1979).

Interplanting is another possibility, in that the valuable but demanding tree species such as walnut are grown together with slower growing, undemanding alder or Russian olive trees which form nitrogen-rich soil (Campbell and Dawson, 1989). Furthermore, small-scale production of seabuckthorn berries (*Hippophae rhamnoides*) is recommended on marginal lands or in mountainous areas (<http://www.hort.purdue.edu/newcrop/>) to yield alcohol, vitamin A and C-rich juice, and a variety of jams, candies and “natural” products (<http://www.genres.de/bmlfao/natber3.htm>). Finally, several undemanding ornamentals plants are actinorhizals, prominent among them *Alnus cordata*, *Hippophae rhamnoides*, *Elaeagnus* spp. and *Ceanothus* spp.

Africa, Asia and Oceania

Casuarina spp., which produce dense and hard wood and have few if any diseases (Dommergues et al., 1999), are now widely used in tropical climates for planting on sand dunes and other marginal sites (Diem and Dommergues, 1990). *Casuarina* spp., especially of *Casuarina equisetifolia*, planted in Africa, India and China's sea-coasts as windbreak are now commonplace (Midgley et al., 1986). For instance, up to a million hectares have thus been planted in China (Turnbull, 1983). In Egypt, *Casuarina* spp. are planted in individual fields where not only does it protect against wind but also it provides fuel wood (El-Lakany, 1990). *Gymnostoma* spp. have been used for re-vegetation of nickel mine spoils in New Caledonia (McCoy et al., 1996). *Casuarina equisetifolia* may increase the soil's nitrogen from 80 kg·ha⁻¹ to more than 300 kg·ha⁻¹ (Dommergues et al., 1999). *Coriaria* spp. have been planted to stabilize hilly areas in Pakistan (Chaudhary and Mirza, 1987). *Alnus nepalensis*, the first plant that appears on landslides and abandoned farmlands in Northeastern India, is used in mixed plantations with cardamom and tea and to re-vegetate degraded lands (Dommergues et al., 1999).

Conclusion

Few groups of microbes are composed of such contrasting families with ecological niches and physiological characteristics as diverse as the one described here. It is only the advent of molecular techniques that has permitted the close proximity of the thermoacidophile Acidothermaceae, the soil Geodermatophilaceae and Sporichthyaceae, and the plant symbionts Frankiaceae to be recognized. The evolutionary history of this group remains to be established and the genome

sequence of *Frankia* and its neighbors will certainly be revealing.

The Family Thermomonosporaceae: *Actinocorallia*, *Actinomadura*, *Spirillospora* and *Thermomonospora*

REINER MICHAEL KROPPESTEDT AND MICHAEL GOODFELLOW

Phylogeny and Taxonomy

The application of chemosystematic and molecular systematic methods has clarified the taxonomic position of the family Thermomonosporaceae. This taxon together with the families Nocardiopsaceae and Streptosporangiaceae is classified in the suborder Streptosporangineae, one of the ten suborders of the order Actinomycetales (Stackebrandt et al., 1997). The family Thermomonosporaceae (Stackebrandt et al., 1997) emended (Zhang et al., 2001) includes the genera *Actinomadura* (Lechevalier and Lechevalier, 1970a), *Actinocorallina* (Iinuma et al., 1994) emended (Zhang et al., 2001), *Spirillospora* (Couch, 1963), and the type genus *Thermomonospora* (Henssen, 1957) emended (Zhang et al., 2001). Members of these taxa form a distinct phyletic line in the 16S rRNA gene tree (Zhang et al., 1998; Zhang et al., 2001) and can be distinguished from one another using a combination of morphological, physiological and chemical features (Trujillo and Goodfellow, 1997; Zhang et al., 1998; Miyadoh et al., 2001; Zhang et al., 2001; Trujillo and Goodfellow, 2003).

Since the second edition of the *The Prokaryotes* many changes have occurred in the classification of the family Thermomonosporaceae: 1) the so called “*Actinomadura* (*Microtetraspora*) *pusilla* group” has been transferred to the new genus *Nonomuraea* (Zhang et al., 1998); 2) *Actinomadura aurantiaca*, *A. glomerata*, *A. libanotica* and *A. longicatena* have been transferred to the genus *Actinocorallia* (Zhang et al., 2001); 3) *Thermomonospora alba*, *T. fusca* and *T. mesoviformis* to the genus *Thermobifida* (Zhang et al., 1998); 4) *Thermomonospora formosensis* and *T. mesophila* to the genus *Actinomadura* (Zhang et al., 2001); and 5) *Spirillospora* from the family Streptosporangiaceae to the family Thermomonosporaceae (Stackebrandt et al., 1997).

The family Thermomonosporaceae was proposed for a morphologically diverse group of organisms classified in the genera *Actinomadura*, *Microbispora*, *Microtetraspora*, *Saccharomonospora* and *Thermomonospora* (Cross and

Goodfellow, 1973). This avowedly heterogeneous assemblage was nevertheless seen to include genera that had more in common than the assortment of organisms previously classified in the family Nocardiaceae, an area long regarded as a dumping ground for aerobic actinomycetes (Lechevalier, 1976). The new family encompassed mesophilic and thermophilic actinomycetes that formed heat sensitive, motile and nonmotile spores carried singly, in pairs, or as short chains on aerial hyphae, on both aerial and substrate mycelia, or developed in spore vesicles (sporangia) as in *Spirillospora*. All members of this taxon have a cell wall containing meso-diaminopimelic acid (meso-A₂pm) but no other characteristic amino acids or sugars (wall chemotype III; Lechevalier and Lechevalier, 1970d; Lechevalier and Lechevalier, 1970b). The genus *Saccharomonospora*, which has meso-A₂pm as the diamino acid of the cell wall peptidoglycan and a polysaccharide fraction rich in arabinose and galactose (wall chemotype IV; Lechevalier and Lechevalier, 1970d; Lechevalier and Lechevalier, 1970c), was included in the family as it was considered to share key morphological properties with *Thermomonospora* species. Other wall chemotype III sporoactinomycetes subsequently thought to be related to the genus *Thermomonospora* included the genera *Actinobifida*, *Actinosynnema*, *Nocardiopsis*, *Saccharothrix* and *Streptoalloteichus* (Küster, 1974; Goodfellow and Cross, 1984; Goodfellow, 1989a; McCarthy, 1989).

The application of chemical and molecular systematic methods has provided invaluable data for the classification of actinomycetes above the genus level (Stackebrandt and Woese, 1981a; Goodfellow and Minnikin, 1985; Stackebrandt and Goodfellow, 1990; Stackebrandt et al., 1997; Zhang et al., 2001); such studies have shown that morphological features previously weighted for the circumscription of genera and families have little predictive value (Stackebrandt and Schleifer, 1984; Stackebrandt, 1986; Goodfellow, 1989b). It soon became evident that the family Thermomonosporaceae (Cross and Goodfellow, 1973) contained markedly diverse taxa and that

the genus *Actinomadura* (Lechevalier and Lechevalier, 1970a) included two groups of organisms with little in common (Fischer et al., 1983; Poschner et al., 1985). Ribosomal (r)RNA partial oligonucleotide sequencing (Fowler et al., 1985; Goodfellow et al., 1988) underlined this heterogeneity and showed that *A. madurae*, the type species of the genus, showed a closer affinity to *Thermomonospora curvata* than to the *A. pusilla* group; members of the latter were seen to be related to *Streptosporangium roseum*.

The division of the genus *Actinomadura* into two disparate groups was formally recognized when Kroppenstedt et al. (1990) proposed that the genus be retained for *A. madurae* and related species and that the *A. pusilla* group be reclassified in the genus *Microtetraspora*. On the basis of the results of comparative 16S rDNA sequencing, all members of the former *A. pusilla* group were transferred from the genus *Microtetraspora* to the new genus *Nonomuraea* (Zhang et al., 1998), a proposition raised but never validated by Goodfellow (Goodfellow et al., 1988). Similarly, several genera associated with the genus *Thermomonospora* have been transferred to other suprageneric groups. The genera *Microbispora* and *Microtetraspora* have been assigned to the family Streptosporangiaceae (see The Family Streptosporangiaceae in this volume), and the genera *Saccharomonospora* and *Saccharothrix* to the family Pseudonocardiaceae (see The Family Pseudonocardiaceae in the second edition). The genus *Nocardiopsis* can be sharply separated from the genus *Thermomonospora* (Fowler et al., 1985; Kroppenstedt et al., 1990) and readily distinguished from the poorly studied genera *Actinosynnema* and *Streptoalloteichus*. *Nocardiopsis* is now the type genus of the family Nocardiopsaceae (Stackebrandt et al., 1997), which includes the genera *Thermobifida* (Zhang et al., 1998) and *Streptomonospora* (Cui et al., 2001; Li et al., 2003). These developments leave the genera *Actinomadura*, *Actinocorallina*, *Spirillospora* and *Thermomonospora* as a relatively homogeneous group with respect to their chemical markers and to the other actinomycete families (Stackebrandt et al., 1983a; Stackebrandt et al., 1983b; Kroppenstedt et al., 1990; Zhang et al., 1998; Zhang et al., 2001).

It is becoming increasingly clear that the family Thermomonosporaceae should be retained for aerobic, Gram-positive, non-acid-alcohol-fast, chemo-organotrophic actinomycetes which form a branched substrate mycelium bearing aerial hyphae that differentiate into single or short chains of arthrospores (*Actinomadura*, *Actinocorallia* and *Thermomonospora*; Figs. 1 and 2) or produce spore vesicles that release motile zoospores (*Spirillospora*; Fig. 3). Constituent strains have meso-diaminopimelic acid in

(From Greiner-Mai et al., 1987.) B) *Thermobifida alba*, single spores on relatively stiff sporophores. (Courtesy of F. Korn-Wendisch.) C) *Thermomonospora chromogena*, single spores in clusters. (Courtesy of F. Korn-Wendisch.)

a wall peptidoglycan that lacks characteristic sugars (Lechevalier and Lechevalier, 1970d; Lechevalier and Lechevalier, 1970c), an A1 γ peptidoglycan type (Schleifer and Kandler, 1972), N-acetylated muramic acid (Uchida and Aida, 1977), mixtures of straight and branched

fatty acids, hydrogenated menaquinones with nine isoprenyl units, and large amounts of phosphatidylglycerol (PG), phosphatidylinositol (PI), and phosphatidylinositol mannosides (PIMs), with the occurrence of PG being variable (Kroppenstedt, 1985; Kroppenstedt, 1987; Kroppenstedt et al., 1990). In addition, whole-organism hydrolysates of thermomonosporae usually contain madurose (3-*O*-methyl-D-galactose; Lechevalier and Gerber, 1970b). There are two exceptions to this profile of properties: thermomonosporae and thermophilic *Actinomadura* strains either lack madurose or synthesize it in trace amounts (Kroppenstedt, 1987), whereas actinocorallinae contain the diagnostic phosphatidylethanolamine in addition to the nondiagnostic phospholipids present in the members of other genera of the family Thermomonosporaceae (Inuma et al., 1994). The guanine plus cytosine (G+C) content of the DNA lies within the range 66–72 mol% (Fischer et al., 1983; Poschner et al., 1985; Hasegawa et al., 1986; Miyadoh et al., 1987; Table 2).

Fig. 3. *Spirillospora albida* ATCC 15331. A scanning electron microscopy image of spherical spore vesicles formed on aerial mycelium after 15 days of incubation. (From Vobis and Kothe (1989), with permission.)

The revised genus *Actinomadura* (Zhang et al., 2001) currently accommodates 32 validly described species and a single subspecies (Table 1), the members of which characteristically form nonfragmenting, extensively branched substrate mycelia and aerial hyphae that carry up to 15 arthrospores. Spore chains may be straight, hooked (open loops), or irregular spirals (1–4 turns) and spore surfaces folded, irregular, smooth, spiny or warty. The temperature range for growth is 10–60°C. Actinomadurae contain major proportions of hexahydrogenated menaquinones with 9 isoprenyl units, saturated at sites II, III and VIII, and complex mixtures of fatty acids with hexadecanoic, 14-methylpentadecanoic (*iso*-16:0) and 10-methyloctadecanoic acid (tuberculostearic acid) predominating, i.e., fatty acid type 3a (Kroppenstedt, 1985). The thermophilic actinomadurae *A. rubrobrunea* and *A. viridilutea*, formerly *Excellospora* (Agre and Guzeva, 1975), can be separated from the mesophilic actinomadurae by differences in fatty acid composition. They contain relatively high proportions of *iso*-branched fatty acids (high melting point) and low amounts of 10-methyl branched acids (low melting point), but these differences can be attributed to the thermophilic nature of these strains. A similar effect can be seen in the sugar composition of these strains as whole-organism hydrolysates contain galactose, glucose, mannose, and ribose with madurose present in trace amounts if at all.

The generic name *Thermomonospora* was proposed by Henssen (1957) for thermophilic actinomycetes isolated from composted stable manure. The genus contained three species that formed single spores on the aerial mycelium. All of these organisms produced colorless to

Symbol and abbreviations: *Actm*, *Actinomaduria*; *Acr*, *Actinocorallina*; *Mbs*, *Microbispora*; *Nmr*, *Nonomuraea*; *Spl*, *Spirillospora*; *Tbf*, *Thermobifida*; *Tms*, *Thermomonospora*.

^aAll organisms lack mycolic acids and contain *N*-acetylated muramic acid ⁽ⁱ⁾ apart from the *Nocardia* strains which contain mycolic acids ⁽ⁱ⁾ and have *N*-glycolated ⁽ⁱ⁾ muramic in the wall peptidoglycan. ND, not determined; and () , genera names which changed since the second edition of "The Prokaryotes."

^bMajor constituents in cell walls type: I, LL-diaminopimelic acid (LL-A₃pm); II, *meso*-A₃pm direct; III, *meso*-A₃pm direct, arabinose and galactose (Lechevalier and Lechevalier, 1970). The wall chemotypes correspond to the following peptidoglycan types (Schleifer and Kandler, 1972): I with A₃ γ and III and IV with A1 γ.

^cWhole-organisms sugar patterns of actinomycetes containing *meso*-A₃pm: A, arabinose and galactose; B, madurose (3-*O*-methyl-D-galactose); C, no diagnostic sugars; E, rhamnose; –, not applicable (Lechevalier and Lechevalier, 1970a; Lechevalier and Lechevalier, 1970c; Lechevalier and Lechevalier, 1970d; Lechevalier et al., 1971; Labeda et al., 1984).

^dAbbreviations of phospholipids: PC, phosphatidylcholine; PE, phosphatidylethanolamine; OH-PE, hydroxy-phosphatidylethanolamine; l-PE, lyso-phosphatidylethanolamine; PME, phosphatidylmethylethanolamine. Other nondiagnostic phospholipids may also be found, i.e., DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PI, phosphatidylinositol, and PIM, phosphatidylinositol mannosides. The occurrence of OH-PE is species specific in *Streptomyces* (R. M. Kroppenstedt, unpublished results).

^ePhospholipid types according to Lechevalier et al. (1977) and Lechevalier et al. (1981).

^fAbbreviations exemplified by MK-9(H₆), menaquinones having three of the nine isoprene units saturated (Collins and Jones, 1981; Kroppenstedt et al., 1981; Collins et al., 1982; Collins et al., 1984; Collins et al., 1988; Athalye et al., 1984): 9(H₆)¹ = MK-9(II, III, VIII H₆), saturated isoprene units in positions two, three and eight (Batrakov et al., 1976; Batrakov and Bergelson, 1978; Kroppenstedt, 1982; Yamada et al., 1982a); 9(H₄)² = MK-9(III, VIII H₄), saturated isoprene units in positions three and eight (Collins et al., 1988); 8(H₄₋₆)³ = MK-8(H₄₋₆-cycl.), i.e., II, III-tetrahydro-ω-(2,6,6-trimethylcyclohex-2-enylmethyl) menaquinone-6 (Collins et al., 1988; Howard et al., 1986; Kroppenstedt, 1982); 9(H₆)⁴ = MK-9(II, III, IX H₆) (Yamada et al., 1982b).

^gMenaquinone types according to Kroppenstedt (1985) exemplified by: type one, no hydrogenation of isoprene chain, e.g., MK-9; type two, only one di- or tetrahydrogenated menaquinone present, e.g., MK-9(H₄), and type three, tetrahydrogenated multiprenyl menaquinones, e.g., MK-9(H₄) + MK-10(H₄), and type four, menaquinones with mainly the same isoprenoid chain length but increasing degrees of hydrogenation, e.g., MK-9(H₄), MK-9(H₆), and MK-9(H₈). The position of the double bonds in the isoprene chain can be diagnostic, e.g., MK-9(II, III-H₄) in *Saccharothrix vis-avis* MK-9(II, VIII-H₄) in *Microtetraspora*; 4A1 against 4A2; another example is MK-9(II, III, VIII-H₆) in *Actinomaduria vis-avis* MK-9(II, III, IX-H₆) in *Streptomyces*, 4B1 against 4B2 (Kroppenstedt, 1985; Kroppenstedt, 1987).

^hFatty acid types according to Kroppenstedt (1985) and Kroppenstedt and Kutzner (1978); compositions of the fatty acid types are shown in Table 4 of The Family Nocardiopsaceae in this Volume.

ⁱAll strains contain *N*-glycylglucosamine in the cell wall detected using the simple glycolate test (Uchida and Aida, 1977).

^jAll strains synthesize mycolic acids, α-branched β-hydroxylated long-chain fatty acids (Minnikin et al., 1975).

Data taken from Kroppenstedt (1987) and R. M. Kroppenstedt (unpublished data), *Bergey's Manual of Systematic Bacteriology*, volume 4 (Williams et al., 1989), Kudo et al. (1993), Itoh et al. (1995), Zhang et al. (2001), and Li et al. (2003).

pale yellow colonies and a white aerial mycelium but were distinguished from one another by aerial mycelium morphology and the type of branching shown by the substrate hyphae. *Thermomonospora curvata*, the only species isolated and maintained in pure culture, was later named as the type species of the genus (Henssen and Schnepf, 1967). The description of the remaining two species, *Thermomonospora fusca* and *Thermomonospora lineata*, was based on morphological properties in contaminated preparations. Neither of these species was included in the Approved Lists of Bacterial Names (Skerman et al., 1980) even though *Thermomonospora fusca* had in the meantime been isolated in pure culture and described in detail (Crawford, 1975; Crawford and Gonda, 1977). The name "*Thermomonospora fusca*" was validated (Moore et al., 1985), but this taxon was later transferred to the genus *Thermobifida* on the basis of comparative 16S rDNA sequencing results (Zhang et al., 1998). A mesophilic monosporic actinomycete was assigned to the genus as *Thermomonospora mesophila* (Nonomura and Ohara, 1971c) but was later transferred to the genus *Microbispora* as *Microbispora mesophila* (Miyadoh et al., 1990). A second mesophilic species, *Thermomonospora mesouviformis* (Nonomura and Ohara, 1974), was assigned to the genus *Thermobifida* as a synonym of *Thermobifida alba* (Zhang et al., 1998). A third mesophilic species, *Thermomonospora formosensis*, was described by Hasegawa et al. (1986) but cited as a species incertae sedis in *Bergey's Manual of Systematic Bacteriology* by McCarthy (1989). This species was reclassified by Zhang and coworkers and transferred to the genus *Actinomadura* as *A. formosensis* (Zhang et al., 1998).

Krassil'nikov and Agre (1964a) proposed the genus *Actinobifida* for actinomycetes that formed single spores on dichotomously branched sporophores, but they failed to mention that dichotomous branching had previously been observed in the genus *Thermomonospora* (Henssen, 1957) and in species of *Micromonospora* (Jensen, 1930; Jensen, 1932; Krassil'nikov, 1941). The following year these workers introduced a second species, *Actinobifida chromogena*, and in doing so, suggested that all actinomycetes showing dichotomous branching be transferred to the genus *Actinobifida*. A third species, *Actinobifida alba*, was proposed by Locci et al. (1967). *Actinobifida dichotomica*, the type species of the genus, was later transferred to the genus *Thermoactinomyces* given its ability to produce endospores, and *Actinobifida alba* was transferred to the genus *Thermomonospora* as it formed heat-sensitive spores on substrate and aerial hyphae (Cross and Goodfellow, 1973).

A comprehensive numerical taxonomic survey of the genus *Thermomonospora* and related organisms (McCarthy and Cross, 1984b; McCarthy and Cross, 1984c) confirmed the status of *T. curvata* and provided strong evidence for the formal recognition of *T. fusca*. In contrast, *T. mesouviformis* was considered to be a synonym of *T. alba*. These taxa, termed the "white *Thermomonospora* group" because of their white aerial mycelium, were sharply distinguished from organisms which included the type strain of *Actinobifida chromogena* (Krassil'nikov and Agre, 1965), "*Thermomonospora falcata*" (Henssen, 1970), and similar actinomycetes from mushroom compost (McCarthy and Cross, 1981). The "*chromogena*" strains with reddish-brown colonies and a light brown aerial mycelium had been provisionally included in the genus *Thermomonospora* (Cross, 1981) because of their wall composition and morphology. In the meantime *Thermomonospora viridis* (Küster and Locci, 1963) had been transferred to the genus *Saccharomonospora* (Nonomura and Ohara, 1971c).

Members of the genus *Spirillospora*, which were originally assigned to the family Streptosporangiaceae, may be easily confused on morphological grounds with members of some species of the genus *Streptosporangium*. All strains belonging to these taxa have multisporous, usually spherical spore vesicles carried on aerial hyphae, but members of the genus *Spirillospora* produce zoospores whereas zoospores have never been detected in members of the genus *Streptosporangium*. Nevertheless, it is evident from nucleic reassociation studies, comparative 16S rDNA sequencing, and chemical data that members of the genus *Spirillospora* belong to the family Thermomonosporaceae (Stackebrandt et al., 1981b; Goodfellow, 1989b; Stackebrandt et al., 1997; Zhang et al., 2001). Like other members of this family, the type strain of *Spirillospora albida* has a type I polar lipid pattern (Lechevalier et al., 1981) and a type 3a fatty acid profile (Kroppenstedt, 1985) though previous workers reported a type II phospholipid pattern for *S. albida* ATCC 14541^T (Hasegawa et al., 1978; Lechevalier et al., 1981).

Combining the descriptions of Henssen (1957), Couch (1963), McCarthy and Cross (1984b), McCarthy and Cross (1984c), Goodfellow et al. (1988), Vobis and Kothe (1989), Meyer (1989a), Meyer (1989b), Kroppenstedt et al. (1990), Goodfellow (1992), Kroppenstedt and Goodfellow (1992), Inuma et al. (1994), Kudo (1997), Stackebrandt et al. (1997), Zhang et al. (1998), and Zhang et al. (2001)), the family Thermomonosporaceae can be described as follows: Aerobic, Gram-positive, non-acid-fast, chemo-organotrophic actinomycetes which

produce a branched substrate mycelium which bears aerial hyphae that differentiate into either single or short chains of arthrospores or spore vesicles containing zoospores. The G+C content of the DNA lies in the range 66–72 mol%. The family Thermomonosporaceae contains four genera, namely *Thermomonospora*, *Actinocorallia*, *Actinomadura* and *Spirillospora*, which form a distinct clade in the suborder Streptosporangineae and are closely related to members of the families Streptosporangiaceae and Nocardio-
saceae. Members of the family Thermomonosporaceae share the same cell wall type (type III; meso-diaminopimelic acid), a similar menaquinone profile type 4B2 sensu Kroppenstedt (1985) [MK-9(H₄), MK-9(H₆) and MK-9(H₈)], in which MK-9(H₆) is predominant, and a fatty acid profile type 3a (Kroppenstedt, 1985), properties that differentiate them from members of the families Nocardio-
saceae and Streptosporangiaceae. The presence of madurose is variable, but this sugar can be found in members of most species of the family. The polar lipid profiles are characterized as phospholipid type PI sensu Lechevalier et al. (1977), which indicates the presence of PIM, PI, PG, and diphosphatidyl glycerol (DPG) in most species of *Thermomonospora*, *Actinomadura* and *Spirillospora*; *Actinocorallia* strains are characterized by a phospholipid type PII because of the presence of phosphatidylethanolamine (PE). Further studies need to be performed to clarify the taxonomic position of three *Actinomadura* species, *Spirillospora rubra*, and *Thermomonospora chromogena*. Comparative 16S rDNA sequencing of thermomonosporae (Zhang et al., 2001) revealed that *Thermomonospora curvata*, *Actinomadura echinospora* and *A. umbrina* form a fairly stable clade (bootstrap value 63%) which is separated from one containing the rest of the *Actinomadura* species, apart from *A. spadix*, which is distinct from all of the other members of the family. The separate position of *A. spadix*, is supported by numerical phenetic data (Athalye et al., 1985) and by an electrophoretic mobility study of ribosomal protein AT-L30 (Ochi et al., 1991). *Spirillospora albida*, the type species of *Spirillospora*, is closely related to many *Actinomadura* species. The 16S rRNA gene sequence similarity of *S. albida* to some *Actinomadura* strains is significantly higher than most similarity scores between representatives of *Actinomadura* species. In contrast, *S. rubra* is only distantly related to *S. albida* and to the other species of the family Thermomonosporaceae, which suggests that *Spirillospora rubra* may merit an independent genus status (Zhang et al., 2001).

The family Thermomonosporaceae, as defined above, encompasses the genera *Actinocorallia*

and *Actinomadura* and the two additional genera that encompass *Spirillospora albida*, *S. rubra*, and *Thermomonospora curvata* and *T. chromogena* (Table 1; Fig. 4).

Habitat

Habitats of *Actinomadura* and *Actinocorallina*

Actinomadura and *Actinocorallina* species are widely distributed in soil (Nonomura and Ohara, 1971a; Nonomura and Ohara, 1971d; Preobrazhenskaya et al., 1978; Meyer, 1979; Athalye et al., 1981b; Labeda et al., 1985; Miyadoh et al., 1987; Iinuma et al., 1994; Trujillo and Goodfellow, 2003), where they probably have a role in the turnover of organic matter. *Actinomadura latina*, *A. madurae* and *A. pelletieri* are agents of actinomycete mycetoma. *Actinomadura latina* and *A. pelletieri* have only been isolated from clinical material, but *A. madurae* seems to be widespread in soil. Isolates of the latter from environmental samples lack the red endopigment of clinical isolates and sporulate more readily. The red pigments are characterized by a tripyrrole skeleton and have been identified as cyclononylprodiginine, nonylprodiginine and undecylprodiginine (Gerber, 1971; Gerber, 1973; Lechevalier et al., 1971).

Information on the occurrence and frequency of *Actinomadura* species in different soils has mainly been provided by Preobrazhenskaya and her coworkers (Preobrazhenskaya et al., 1978; Chormonova and Preobrazhenskaya, 1981; Galatenko et al., 1981; Terekhova et al., 1982), who found that the total number of *Actinomadura* strains was higher in cultivated than in uncultivated soil. The highest number of actinomadurae was isolated from chernozem soil (Kazakhstan) and the lowest from sierozem soil (Turkmenistan). Dark chestnut soil (cultivated) contained half the number of actinomadurae found in the chernozem soil, but the species diversity in each of the soil types was similar. *Actinomadura citrea* was the most frequent species in the uncultivated and cultivated soils, followed by *A. cremea* and *A. verrucosospora*. *Actinomadura viridilutea* was isolated from an arid soil from the Soviet Union, and *A. rubrobrunea* was isolated from Egyptian soils under maize and rice (Agre and Guzeva, 1975). There is evidence that both clinically and ecologically significant actinomadurae are underspeciated (Trujillo and Goodfellow, 2003).

Habitats of *Spirillospora*

Members of the genus *Spirillospora* occur in soil, albeit infrequently. They may be isolated from

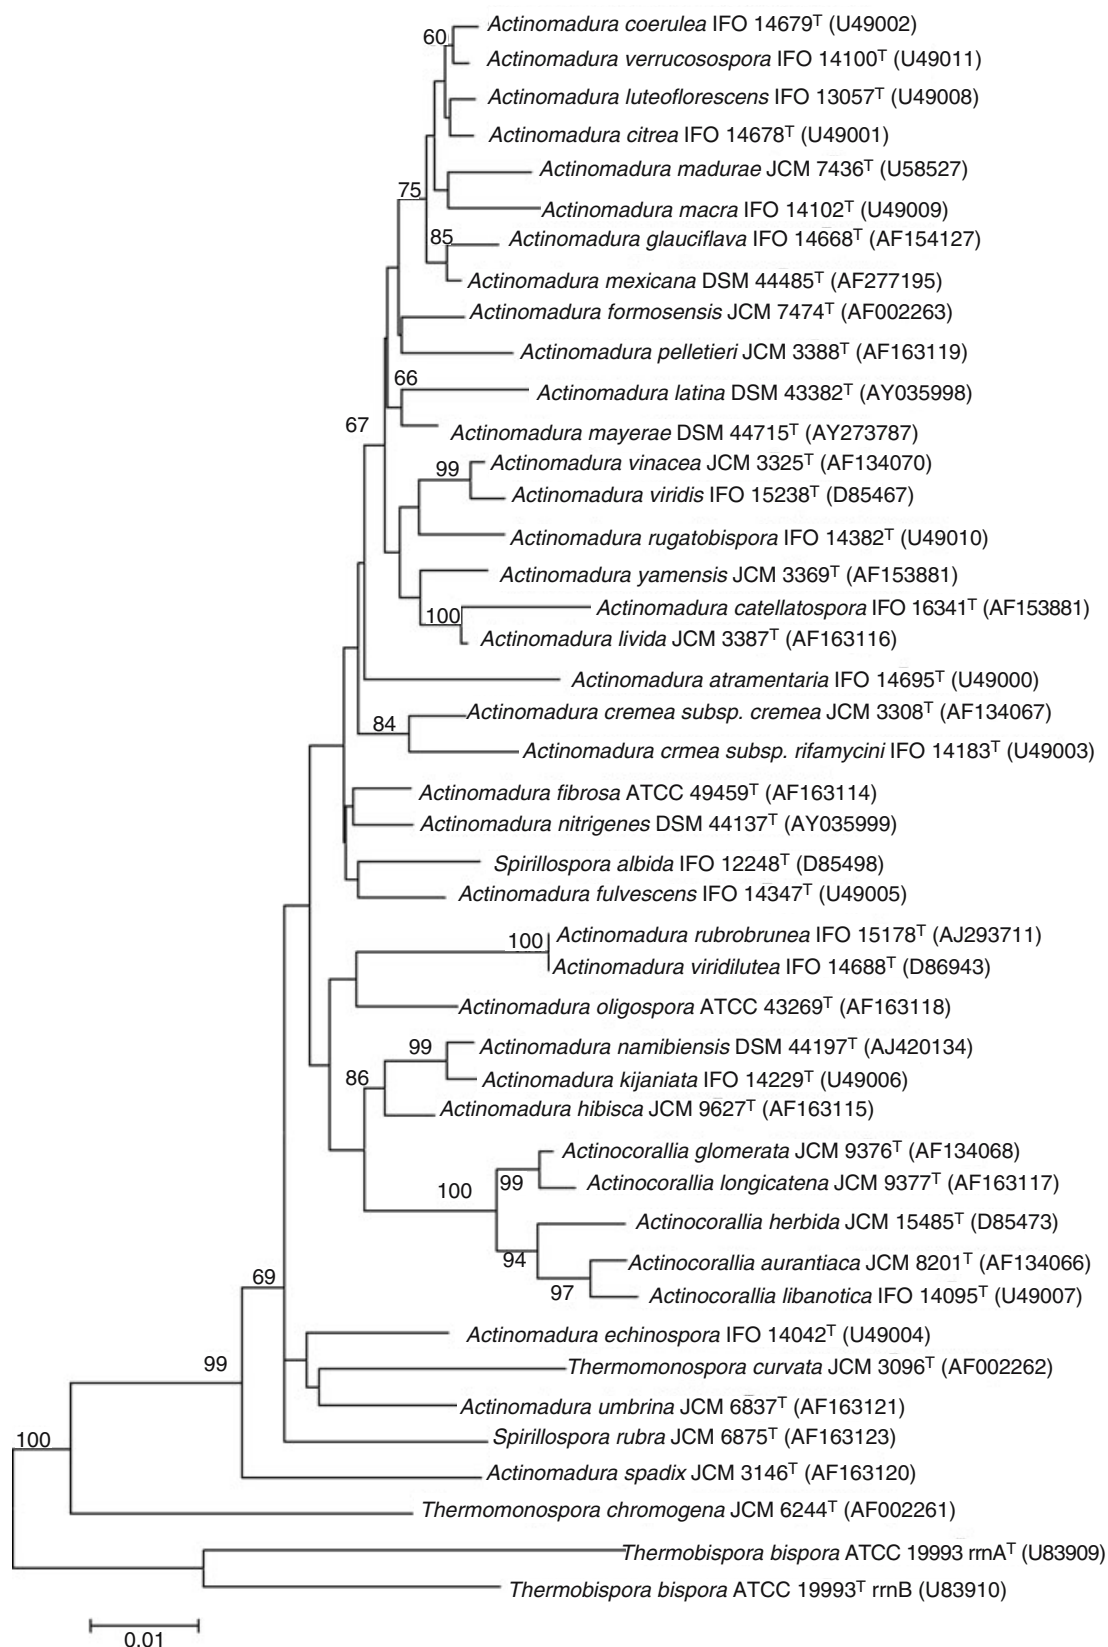

Fig. 4. Neighbor-joining tree (Saitou and Nei, 1987) based on nearly complete 16S rDNA sequences showing the relationship between members of the family Thermomonosporaceae. The numbers at the nodes indicate levels of bootstrap support based on a neighbor-joining analysis of 1000 resampled datasets; only values above 50% are given. Scale indicates 0.01 substitutions per nucleotide position. T, type strain.

this milieu by applying the bait technique (using pollen for the isolation of *S. alba* or hair for the recovery of *S. rubra*); these organisms account for less than 1% of the "sporangiate" actinomycetes isolated from soil using baits (Schäfer, 1973).

Habitats of *Thermomonospora*

The ability of thermomonosporae to secrete a variety of thermostable extracellular enzymes enables them to become established as dominant populations during high temperature composting of plant residues and other wastes (Fergus, 1964; Stutzenberger, 1971; Bernier et al., 1988b). In addition to the true *Thermomonospora* species (i.e., *T. curvata* and *T. chromogena*), other thermophilic monosporic actinomycetes need be considered here because it is possible that strains assigned to the species may belong to the genus *Thermobifida*, a genus of the family Nocardiopsaceae (Zhang et al., 1998).

Thermophilic thermomonosporae are common in overheated substrates such as bagasse, compost, fodders and manures. They are especially abundant in mushroom compost (Fergus, 1964; Lacey, 1974; Lacey, 1977; McCarthy and Cross, 1981; McCarthy and Cross, 1984b) and are highly cellulolytic (McCarthy, 1987; Ball and McCarthy, 1988) or hemicellulolytic or both (McCarthy et al., 1985; McCarthy et al., 1988). *Thermomonospora curvata* and *Thermobifida fusca* strains show endoglucanase activity and attack cellulose. The production of endoglucanase (e.g., cellobiohydrolase) by thermomonosporae is currently regarded as unsubstantiated. *Thermomonospora* strains also grow on rape-seed that has been subject to heat damage during storage (Mills and Bollen, 1976).

Thermomonosporae can extensively degrade cellulose and lignocellulose residues that make up the bulk of agricultural and urban wastes (McCarthy, 1987a; McCarthy, 1987b). *Thermomonospora curvata* is active in the decomposition of municipal waste compost (Stutzenberger et al., 1970; Stutzenberger, 1971; Stutzenberger, 1972a; Stutzenberger, 1972b); heavy metals in such composts have been shown to inhibit cellulase production (Stutzenberger and Sterpu, 1978). Similarly, thermomonosporae are very active against arabinoxylan and produce enzymes that have thermostability properties (McCarthy et al., 1985). Evidence that cellulase decomposition in mushroom compost involves a positive interaction between cellulolytic actinomycetes and certain bacteria (Staneck, 1972) underlines the importance of considering natural lignocellulose degradation as the product of an interactive heterogeneous microflora.

Isolation and Cultivation

Isolation and Cultivation of *Actinomadura*

Noncontaminated clinical samples, such as pus and biopsy material, thought to contain clinically significant actinomadurae, notably *A. madurae* and *A. pelletieri*, should be inoculated into media such as brain heart infusion (Oxoid CM261; Schaal, 1972), Sabouraud dextrose (Gordon, 1974) and yeast extract agars (Pridham et al., 1956–57). Media should be transparent to facilitate direct microscopic examination of colonies. Selective isolation media need to be used for the examination of clinical material that contains large numbers of other microbes. Actinomadurae form small colonies on media selective for nocardiae (see The Families Nocardiaceae Dietziaceae, Gordoniaceae, and Tsukamurellaceae in this Volume). All cultures should be inoculated aerobically at 2–27°C and at 36°C for up to three weeks and examined both macroscopically and microscopically for growth every two days (Schaal, 1984a). Actinomadurae can be recognized by their filamentous appearance, by leathery colonies, and by the production of red prodiginine pigments. Actinomycetoma granules should be washed in sterile tap water before they are crushed to obtain material for inoculation of culture media.

Media formulations supplemented with antifungal antibiotics such as actidione and cycloheximide can be used to isolate actinomadurae from environmental samples. Media that have proved to be effective include egg albumin (Lawson and Davey, 1972), glucose yeast extract (Athalye et al., 1981b), glycerol asparagine (ISP medium 5; Shirling and Gottlieb, 1966), inorganic salts and starch (ISP medium 4; Shirling and Gottlieb, 1966), oatmeal (ISP medium 3; Shirling and Gottlieb, 1966) and yeast extract agars (ISP medium 2; Shirling and Gottlieb, 1966). Strains may be isolated from agar plates after incubation for 14–21 days.

Isolation of actinomadurae from enriched soil can be achieved using pretreatment regimes and selective agents. Nonomura and Ohara (1971d) reduced the number of unwanted microorganisms by air-drying soil and applying dry heat at 100°C for 1 h before plating onto various media, notably arginine-vitamins (AV) and mineral-glucose-asparagine (MGA) agars, and incubating for several weeks at 28–30°C. Soviet microbiologists (Lavrova et al., 1972; Preobrazhenskaya et al., 1975b) increased the number of actinomadurae isolated by the addition of antibiotics to medium no. 2 of Gauze et al. (1957); the antibiotics were used to inhibit the growth of bacteria and the more frequently occurring streptomycetes, thereby providing

more favorable conditions for the growth of the slow-growing actinomadurae. Bruneomycin (0.5, 1.0 or 2.0 µg/ml), rubomycin (5.0, 10.0 or 20 µg/ml), and streptomycin (0.5, 1.0 or 2.0 µg/ml) were the most successfully used antibiotics. Athalye et al. (1981b) combined drying and heat pre-treatment regimes with the use of rifampicin (5 µg/ml) as the selective agent. *Actinomadura rubrobrunea* was isolated by scattering crushed soil over the medium of Kosmachev (1960) and incubating at 55°C. Similarly, *A. formosensis* was obtained by plating soil dilutions onto starch casein agar (Waksman, 1961) supplemented with kabicidin (6.25 µg/ml) and rifampicin (12.5 µg/ml; Hasegawa et al., 1986).

Actinomadurae generally grow well on modified Bennett's agar (Jones, 1949), glucose yeast extract agar (Athalye et al., 1981b), and on formulations used for the cultivation of streptomycetes in the International *Streptomyces* Project (ISP; Shirling and Gottlieb, 1966). Most strains show abundant growth on oatmeal agar (ISP medium 3) at 30°C, but *A. kijaniata* and *A. macra* grow better on yeast extract malt extract agar (ISP medium 2). *Actinomadura spadix* requires vitamin B₁₂ for good growth (Nonomura and Ohara, 1971d), and *A. vinacea* grows well on glucose peptone agar but poorly on the media mentioned above. *Actinomadura rubrobrunea* and *A. viridilutea* grow well on oatmeal and peptone maize agars at 50°C.

Isolation and Cultivation of *Actinocorallia*

Members of this genus are widely distributed in soil and can be isolated using the methods described for *Actinomadura* strains. A specific method was described by Iinuma et al. (1994) for *Actinocorallia herbida*, which was isolated from a soil sample in Bangkok, Thailand, by the dilution agar plating method, using colloidal chitin-vitamin agar. The isolate was subcultured on OMH agar containing 2.2% ISP medium 3, 0.1% yeast extract, 0.02% humic acid, and 1.5% agar or on yeast extract malt extract agar (ISP medium 2) at 28°C for 10 days.

Isolation and Cultivation of *Spirillospora*

Spirillospora strains have been recovered from soil by baiting with natural substrates (Couch, 1954; Bland and Couch, 1981). Using the baiting technique, Schäfer (1973) found that less than 1.0% of the isolates of "sporangiate" actinomycetes were represented by this genus. The following method was used: A small amount of soil, approximately one level teaspoonful, is placed in a sterile Petri dish and flooded with sterile water (distilled water or filtrated soil or

charcoal water extracts may be used). Added pollen and hair float at the water surface; various types of pollen have been employed including that from members of the genera *Liquidamber*, *Pinus* and *Sparganium* (Schäfer, 1973). After 1–4 weeks, examination of the water surface with a dissecting microscope (100X) and strong horizontal lighting should reveal the presence of white glistening spore vesicles formed in the air at the surface of the water by "sporangiate" members of the families Micromonosporaceae, Streptosporangiaceae and the genus *Spirillospora* if they are present. The spore vesicles of *Spirillospora albida* develop on long aerial hyphae growing between the baits on the pollen grain whereas *Spirillospora rubra* could only be isolated from hair (Schäfer, 1973). Single spore vesicles can be picked up with a thin needle and placed on the surface of agar media in small Petri dishes. After 2–4 weeks, the young colonies can be transferred to slant cultures. Various complex media support the growth of *Spirillospora* strains. *Spirillospora albida* grows well on Czapek, peptone-Czapek, and oatmeal agars, whereas *S. rubra* prefers half concentrated corn-meal agar (Difco) supplemented with sterilized garden soil (50 g/liter) or half concentrated skim milk agar (Difco; Schäfer, 1973).

Isolation and Cultivation of *Thermomonospora*

Thermophilic *Thermomonospora* strains can be isolated from composts and overheated vegetable material by dilution plating on nonselective media, but recovery is poor owing to the rapid competing growth of *Bacillus* and *Thermoactinomyces* strains. The most effective isolation methods are those based on the use of a sedimentation chamber and an Andersen sampler (Andersen, 1958; Lacey and Dutkiewicz, 1976; McCarthy and Cross, 1981; McCarthy and Broda, 1984a). Dried environmental samples are shaken within the chamber to create an aerosol of propagules that, after 1–2 h of sedimentation, still contains many actinomycete spores but relatively few bacteria. Actinomycetes are isolated from this spore suspension using an Andersen sampler loaded with half-strength tryptone soy agar plates supplemented with cycloheximide (50 µg/ml) to prevent growth of fungi. The recovery of *Thermomonospora* strains can be enhanced by adjusting the isolation medium to a high pH. *Thermomonospora chromogena* strains can grow up to pH 10.0, and *T. curvata* show significant growth even at pH 11 (Kempf, 1995). Cellulolytic isolates may be detected by incorporating cellulose

powder or ball-milled straw into the agar (Stutzenberger et al., 1970; McCarthy and Broda, 1984a).

Thermomonospora colonies can usually be recognized after 3–5 days incubation at 50°C. Care must be taken to distinguish these target colonies from colonies of other filamentous bacteria with white aerial mycelium that grow at increased temperatures, for example, *Streptomyces albus* and *Thermoactinomyces* strains. However, *Thermomonospora* colonies can be spotted by carefully searching isolation plates with a 40X long-working-distance objective and looking for the characteristic single spores on the aerial mycelium. The morphology of pure cultures can be confirmed by observing plate cultures or inclined cover slip preparations as described by Williams and Cross (1971).

Thermomonospora chromogena is readily isolated on selective media containing kanamycin (25 µg/ml; McCarthy and Cross, 1981) or rifampicin (5 µg/ml; Athalye et al., 1981b). *Thermomonosporae* have been isolated from soil samples using the selective procedure that involves heating environmental samples at 100°C prior to preparing suspensions for plating out (Nonomura and Ohara, 1971c; Nonomura and Ohara, 1974). Mixtures of organic matter and soil, inoculated in partially sealed polyethylene bags for a day, yield samples enriched in thermophilic actinomycetes, including thermomonosporae (McCarthy, 1989). Henssen (1957) used an anaerobic enrichment method to isolate her original *Thermomonospora* strains, but the procedure and apparatus involved were unwieldy and may not have produced anything like anaerobic conditions.

Thermomonospora chromogena and *T. curvata* strains grow well at pH 7.5 on any nutrient medium that contains some yeast extract. They are readily cultivated on Czapek peptone agar, glucose-yeast extract-malt extract agar (Greiner-Mai et al., 1987), Hickey and Tresner agar (Hickey and Tresner, 1952), nutrient and peptone-maize agar (Greiner-Mai et al., 1987), and ISP media (Shirling and Gottlieb, 1966) after 2–4 days incubation at their optimal temperature of 50°C (Greiner-Mai et al., 1987).

Media and Techniques for Isolation and Cultivation

The following are the formulae of the media mentioned in the preceding section that are not commercially available. Quantities are diluted to 1 liter with distilled water unless otherwise stated.

AV Agar with Vitamins (Nonomura and Ohara, 1969)

L-Arginine	0.3 g
Glucose	1.0 g
Glycerol	1.0 g
K ₂ HPO ₄	0.3 g
MgSO ₄ · 7H ₂ O	0.2 g
NaCl	0.3 g
Agar	15 g

Adjust to pH 8.0 with NaOH.

Trace Salts Solutions

CuSO ₄ · 5H ₂ O	1.0 mg/ml
Fe ₂ (SO ₄) ₃	10 mg/ml
MgSO ₄ · 7H ₂ O	1.0 mg/ml
ZnSO ₄ · 7H ₂ O	1.0 mg/ml

Adjust pH of each to 8.0.

Vitamins and Antibiotics (dissolve in 10 ml)

<i>p</i> -Aminobenzoic acid	0.5 mg
Calcium pantothenate	0.5 mg
Inositol	0.5 mg
Niacin	0.5 mg
Pyridoxine · HCl	0.5 mg
Riboflavin	0.5 mg
Thiamine · HCl	0.5 mg
Biotin	0.25 mg
Cycloheximide	50 mg
Nystatin	50 mg
Nalidixic acid	0 or 20 mg
Penicillin G 0 or 0.8 mg Polymyxin	0 or 4 mg

Adjust final pH to 6.4.

Add to the sterilized basal medium aseptically, 10 ml of filter sterilized trace salt solution, and 10 ml of filter sterilized Vitamin and Antibiotics solution.

Bennett's Agar (Medium 548, DSMZ Catalogue; Jones, 1949)

Beef extract	1 g
Glucose	10 g
N-Z amine A (enzymatic digest of casein)	2 g
Yeast extract	1 g
Agar	15 g

Adjust to pH 7.3 with NaOH.

Modified Bennett's agar can be used where glucose is replaced by glycerol (10 g) and N-Z amine by Bacto-casein (2 g, Difco).

Chitin-Vitamins Agar (Inuma et al., 1994)

Chitin	1.00 g
KCl	1.71 g
Na ₂ HPO ₄	1.63 g
Agar	18 g
CaCO ₃	20 mg
FeSO ₄ · 7H ₂ O	10 mg
Thiamine · HCl	1 mg
Riboflavin	1 mg
Niacin	1 mg
Pyridoxine · HCl	1 mg
Inositol	1 mg
Calcium pantothenate	1 mg

<i>p</i> -Aminobenzoic acid	1 mg
Biotin	0.5 mg
Cycloheximide	50 mg
Kabicitin	10 mg

Adjust to pH 7.2.

Czapek Agar (Medium 130, DSMZ Catalogue; Waksman, 1950)

Sucrose	30 g
FeSO ₄ · 7H ₂ O	0.01 g
KCl	0.5 g
K ₂ HPO ₄	1.0 g
MgSO ₄ · 7H ₂ O	0.5 g
NaNO ₃	3.0 g
Agar	15 g

Dissolve components, dispense the medium into flasks or tubes, and then autoclave. For peptone-Czapek agar, substitute 5 g of peptone for the 3 g of NaNO₃ (Bland and Couch, 1981).

GYM Agar (Medium 65, DSMZ Catalogue; Greiner-Mai et al., 1987)

Glucose	4 g
Yeast extract	410 g
Malt extract	10 g
CaCO ₃	2 g
Agar	12 g

Adjust to pH 7.2.

Glucose Peptone Agar (Medium 85 DSMZ Catalogue)

Bacto peptone (Difco)	20 g
Glucose	10 g
Yeast extract	10 g
CaCO ₃	10 g
Agar	15 g

Adjust to pH 7.3.

Glucose Yeast Extract Agar (Waksman, 1950)

Glucose	10 g
Yeast extract (50% solution)	20 ml
Agar	15 g

Adjust pH to 7.5.

Hickey and Tresner Agar (Medium 658, DSMZ Catalogue; Hickey and Tresner, 1952)

Dextrin	10 g
Beef extract (Difco)	1 g
NZ amine A or Tryptone (Difco)	2 g
Yeast extract (Difco)	1 g
CoCl ₂ · 6H ₂ O	2 mg
Agar	20 g

Adjust pH to 7.3.

The dextrin "Amidax" (Corn Products Refining Co., Argo, IL, United States) was used in the original formulation.

ISP Medium 2: Yeast Extract-Malt Extract Agar (Medium 987; DSMZ Catalogue; Pridham et al., 1956–57)

Dextrose (Difco)	4 g
Malt extract (Difco)	10 g
Yeast extract (Difco)	4 g

Adjust to pH 7.3, and then add 20 g of Bacto agar. Liquefy agar by steaming at 100°C for 15–20 min.

ISP Medium 3: Oatmeal Agar (Küster, 1959b)

Oatmeal	20.0 g
Agar	18.0 g

Cook or steam 20 g of oatmeal in 1 liter of distilled water for 20 min. Filter through cheesecloth. Add distilled water to restore volume of filtrate to 1000 ml. Add 1 ml trace salt solution (FeSO₄ · 7H₂O, 0.1 g; MnCl₂ · H₂O, 0.1 g; ZnSO₄ · 7H₂O, 0.1 g; and distilled water, 100.0 ml). Adjust to pH 7.5 with NaOH. Add 18 g of agar; liquefy by steaming at 100°C for 15–20 min.

ISP Medium 4: Inorganic Salt-Starch Agar (Medium 547, DSMZ Catalogue; Küster, 1959a)

Solution I

Difco soluble starch	10.0 g
----------------------	--------

Make a paste of the starch with a small amount of cold distilled water and bring to a volume of 500 ml.

Solution II

CaCO ₃	2 g
K ₂ HPO ₄ (anhydrous)	1 g
MgSO ₄ · 7H ₂ O	1 g
NaCl	1 g
(NH ₄) ₂ SO ₄	2 g
Distilled water	500 ml
ISP medium 3 trace salt solution	1 ml

The pH should be 7.0–7.4. Do not adjust if it is within this range. Mix solutions I and II together. Add 20 g of agar. Liquefy agar by steaming at 100°C for 10–20 min.

ISP Medium 5: Glycerol-Asparagine Agar (Medium 993, DSMZ Catalogue; Pridham and Lyons, 1961)

L-Asparagine (anhydrous)	1.0 g
Glycerol	10.0 g
K ₂ HPO ₄ (anhydrous)	1.0 g
ISP medium 3 trace salt solution	1.0 ml

Do not adjust if the pH of this solution is about 7.0–7.4. Add 20 g of agar. Liquefy agar by steaming at 100°C for 15–20 min.

ISP Medium 7: Tyrosine Agar (Shinobu, 1958)

L-Asparagine	1.0 g
Glycerol	15 g
L-Tyrosine	0.5 g
FeSO ₄ · 7H ₂ O	0.01 g
K ₂ HPO ₄ (anhydrous)	0.5 g
MgSO ₄ · 7H ₂ O	0.5 g
NaCl	0.5 g
ISP medium 3 trace salt solution	1.0 ml

Adjust pH to 7.2–7.4. Add 20 g of agar. Liquefy agar by steaming at 100°C for 15–20 min.

Kosmachev's Medium (Kosmachev, 1960)

Yeast autolysate (30% [w/v])	15 ml
CaCO ₃	4 g
FeSO ₄ · 7H ₂ O	0.01 g
KNO ₃	1 g
MgSO ₄ · 7H ₂ O	0.5 g
Na ₂ HPO ₄	1 g
(NH ₄) ₂ SO ₄	1 g
Agar	15 g

MGA Agar (Nonomura and Ohara, 1971b)

L-Asparagine	1 g
Glucose	2 g
K ₂ HPO ₄	0.5 g
MgSO ₄ · 7H ₂ O	0.5 g
Agar	20 g

Add the trace salt solutions as indicated for AV agar with vitamins. Add antibiotics: cycloheximide, 50 mg; nystatin, 50 mg; benzylpenicillin, 0.8 mg; and polymyxin B, 4 mg.

Medium No 2 (Gauze et al., 1957)

Glucose	10 g
Hottinger's broth	30 ml
Peptone	5 g
NaCl	10 g
Agar	15 g

Peptone Corn Meal Agar (Medium 85 831, DSMZ Catalogue; Greiner-Mai et al., 1987)

Corn meal	17 g
Peptone	5 g
Starch	10 g
CaCl ₂ · 2H ₂ O	0.5 g
NaCl	5.0 g
Agar	15 g

Adjust pH to 7.2 before sterilization.

Modified Skim Milk-Mineral Agar (Schäfer, 1973)

Skim milk (powder)	2.5 g
Ca(NO ₃) ₂ · 4H ₂ O	0.5 g
MgSO ₄ · 7H ₂ O	0.7 g
K ₂ HPO ₄	0.005 g
NaHCO ₃	0.2 g
FeCl ₃	0.005 g
Agar	15 g

Autoclave the skim milk powder separately in 100 ml of H₂O and add it to the agar-medium at 60°C.

Starch Casein Agar (Waksman, 1961)

Casein	1.0 g
Soluble starch	10 g
K ₂ HPO ₄	0.5 g
Agar	15 g

Adjust pH to 7.0–7.5.

Preservation

Heavily sporulated cultures are needed to maintain high viability irrespective of the preservation method. The highest survival rates for cultures that do not sporulate are achieved using cells from the logarithmic growth phase. The culture age of the organisms to be preserved is very important especially for the preservation of thermophilic strains that readily lyse at the stationary phase of growth.

Sporulated *Actinomadura* strains can be kept on oatmeal agar, or other suitable agar slants, at 4°C and transferred every four months for short-term preservation. The tubes should be sealed with silicone stoppers to prevent the agar drying out. The same procedure can be used for strains

of *Thermomonospora*, but in this case, cultures should be transferred every one to two months using Czapek Dox-yeast extract-casamino acids agar at pH 8.0 (McCarthy, 1989). Medium-term preservation for up to four years can be achieved by mixing spore suspensions or homogenized mycelia with glycerol (45%, v/v) and storing at –25°C (Zippel and Neigenfind, 1988). Lyophilization of spores and mycelia suspended in 10% skim milk is a convenient method for long-term storage. An alternative simple, reliable and quick method involves nitrogen cryopreservation of living cells in small polyvinyl chloride tubes ("straws") at –196°C (Hoffmann, 1989a; Hoffmann, 1989b). This procedure has been shown to be reliable for actinomycetes, including *Actinomadura*, *Actinocorallina*, *Spirillospora* and *Thermomonospora* (see The Family Nocardiopsaceae in this Volume).

Identification

Members of the genera *Actinomadura*, *Actinocorallina*, *Spirillospora* and *Thermomonospora* can be distinguished from all other actinomycetes using a combination of chemical and morphological features. Primary diagnostic information can be gained by the detection of marker amino acids, fatty acids, menaquinones, sugars, and polar lipids (Table 2). Simple procedures have been devised for the detection of these chemical features (Staneck and Roberts, 1974; Lechevalier and Lechevalier, 1980; Minnikin et al., 1984; Kroppenstedt, 1985).

One-dimensional thin-layer chromatography will determine if an organism contains diamidinopimelic acid and whether the latter is in the LL- or *meso*-form. The presence of LL-A₂pm will lead to *Streptomyces* and related genera (see The Family Streptomycetaceae, Part I in this Volume and The Family Streptomycetaceae, Part II in this Volume). The detection of various combinations of *meso*-A₂pm, mixtures of straight and branched chain fatty acids, predominant amounts of hexahydrogenated menaquinones with nine isoprene units, and large amounts of DPG, PG and PI (phospholipid type I sensu Lechevalier et al. [1977]) can be used to separate strains of *Thermomonospora*, *Actinomadura* and *Spirillospora* from all other sporoactinomycetes, notably those classified in the families Actinoplanaceae (see The Family Actinomycetaceae in this Volume), Nocardiaceae (see The Family Nocardiaceae in this Volume), Pseudonocardiaceae (including *Saccharothrix*) (see The Family Pseudonocardiaceae in the second edition) and Streptosporangiaceae (see The Family Streptosporangiaceae in this Volume), and in the genus *Thermoactinomyces*. The reports on the phospholipid composition of *Spirillospora albida*

Table 2. Taxonomic history of actinomycetes designated or once assigned to the genera *Actinomadura*, *Actinocorallia*, *Spirillospora* and *Thermomonospora*.

are confusing. One group detected DPG, PG and PI in *Spirillospora albida* (PL-type one; Lechevalier et al., 1977), whereas another group found phosphatidylethanolamine (PE) as an additional component (PL-type II; Hasegawa et al., 1979).

Actinocorallina, like the other members of the family Thermomonosporaceae, falls into maduromycetes taxon. The name "maduromycetes" was proposed by Goodfellow (Goodfellow, 1989b; Goodfellow, 1989a) for sporoactinomycetes able to synthesize madurose, a sugar which is always present in whole-cell hydrolysates of members of the closely related families Thermomonosporaceae and Streptosporangiaceae. Madurose, a 3-*O*-methylgalactose (Lechevalier and Gerber, 1970b), got its name from *A. madurae* as it was found for the first time in this actinomycete (Lechevalier and Lechevalier, 1970c). *Actinocorallina* can be differentiated from the other maduromycetes by its phospholipid pattern type II: from members of the family Thermomonosporaceae, i.e., type II versus type I and from Streptosporangiaceae, type II versus type IV. All members of the family Thermomonosporaceae have the menaquinone type 4B2 in common, whereas in members of the family Streptosporangiaceae, the type 4A2 is found (Table 2). This is one of the examples of good correlation between chemotypes and genotypes in members of the order Actinomycetales.

Thermomonosporae in the broad sense are similar but not related to thermoactinomycetes with respect to morphology, cell wall chemotype, and natural habitat. The detection of endospores in the latter separates them from thermomonosporae and all other monosporic actinomycetes. The genera *Actinosynnema* (Hasegawa et al., 1978) and *Streptoalloteichus* (Tomita et al., 1987) were proposed for actinomycetes considered to be morphologically unusual. The morphology of members of the two taxa is complex and differs fundamentally from *Actinomadura*, *Actinocorallina* and *Thermomonospora* strains as motile spores are produced. Members of the two genera can be differentiated from *Spirillospora* by the type of zoospore produced and the presence of spore vesicles. In *Actinosynnema*, peritrichously flagellated zoospores originate from aerial spore chains borne on synnemata, whereas in *Streptoalloteichus*, spores propelled by single polar flagella are formed in sporangium like vessels carried on substrate hyphae, which show some similarities with those of *Spirillospora*. *Streptoalloteichus* strains also produce chains of *Streptomyces*-like arthrospores on aerial hyphae.

The genus *Actinomadura* can be distinguished from other sporoactinomycete taxa using a judicious selection of chemical and morphological

features (Meyer, 1989a; Meyer, 1989b; Kroppenstedt et al., 1990; Wink, 2002; Tables 2 and 3). Quantitative analyses of fatty acid data allow the separation of mesophilic actinomadurae from corresponding members of the genera *Microtetraspora*, *Nocardopsis*, *Saccharothrix* and *Thermomonospora* (Kroppenstedt, 1987). Actinomadurae and microtetrasporae can also be distinguished on the basis of menaquinone and polar lipid profiles (Figs. 5 and 6).

Members of *Actinomadura* and *Actinocorallina* species can be separated using biochemical, morphological, pigmentation and physiological properties (Tables 3–6). However, identification of most of these species is difficult, for in many instances, only one representative organism, usually the type strain, has been examined. Even when several representatives of species have been studied, the results of biochemical and physiological tests have proved to be variable or inconsistent when data from the literature are compared. Even so, numerical taxonomic evidence shows that many of the validly described taxa do merit species status (Goodfellow et al., 1979; Goodfellow and Pirouz, 1982; Athalye et al., 1985; Trujillo and Goodfellow, 1997; Trujillo and Goodfellow, 2003). It is also encouraging that *Actinomadura* species have been shown to form distinct genomic species (Fischer et al., 1983; Poschner et al., 1985; Zhang et al. 1998; Zhang et al., 2001).

Clinically significant actinomadurae (such as *Actinomadura madurae* and *A. pelletieri*) can be separated from each other and from other pathogenic aerobic actinomycetes, notably as *Streptomyces somaliensis*, *Rhodococcus equi*, *Nocardia* spp., *Gordonia* spp., *Tsukamurella* spp. and *Mycobacterium* spp., by DNA amplification and restriction endonuclease analysis. Steingrube et al. (1997) used the two primers TB11 and TB12 for amplification of the 439-bp segment (amplicon) of the 65-kDa shock protein to differentiate between the type strains of representative species and clinically significant isolates. The amplicon was cleaved by five restriction endonucleases, namely *Bst*EII, *Hae*III, *Hinf*I, *Msp*I, and *Bsa*HI. This polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) methodology distinguished between clinical isolates of aerobic actinomycetes including actinomadurae with 96.8% accuracy.

Members of the redefined *Thermomonospora* share chemical markers in common with *Actinomadura* strains, i.e., wall chemotype III, phospholipid type I, menaquinone type 4B2, and fatty acid type 3a (Table 2; Fig. 6). The integrity of the group containing *T. curvata* and *T. chromogena* is also supported by fatty acid and menaquinone data. Variations in the quantitative fatty acid

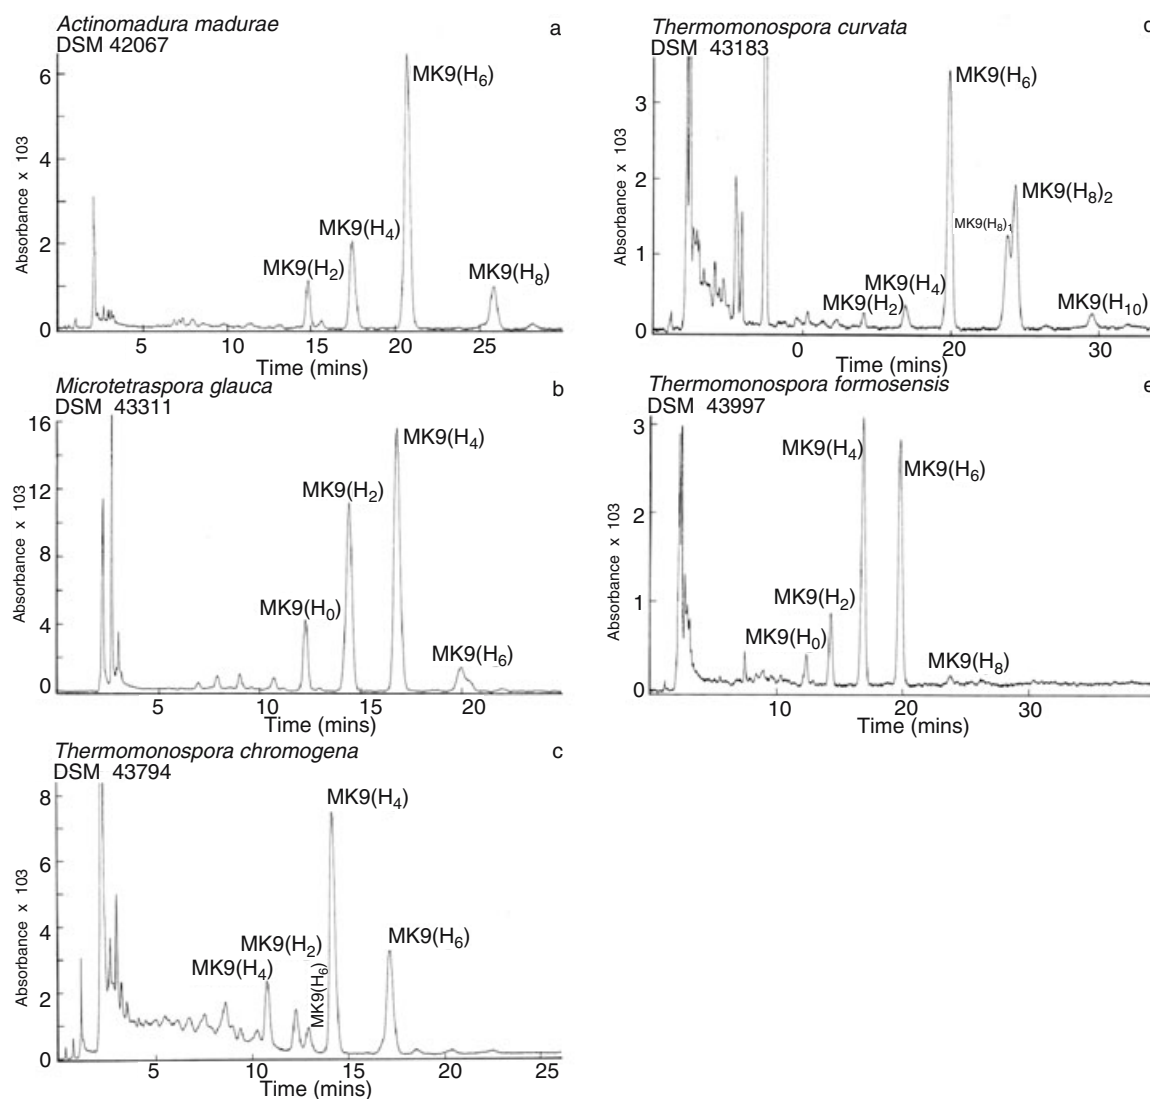

Fig. 5. Menaquinone profiles of: a) *Actinomadura madurae* DSM 43067^T, b) *Microtetraspora glauca* DSM 43311^T, c) *Thermomonospora chromogena* DSM 43794^T, d) *Thermomonospora curvata* DSM 43183^T and e) *Actinomadura formosensis* DSM 43997^T.

Chromatographic conditions: column, 250 mm × 4 mm; stationary phase, RP 18, size 5 µm; mobile phase, acetonitrile-isopropanol (65:35, v/v); flow rate, 1 ml/min; temperature 40°C; injection volume, 5 µl of extract prepared after Minnikin et al. (1984) without further purification. Key to abbreviations: see table 2.

composition and in the menaquinone profiles of *T. curvata* and *T. chromogena* with respect to other members of this family may be attributed to differences in their temperature requirements for growth (Kroppenstedt et al., 1990). The lack of madurose (sugar type C) might be an effect of the elevated temperature for growth, because in members of thermophilic *Actinomadura* species (formerly *Excellospora*) this sugar is found only in traces. *Thermomonospora chromogena* and *Thermobifida fusca* can be distinguished from one another and from strains of other monosporic taxa previously assigned to the genus *Thermomonospora* (Table 7).

Members of the genus *Spirillospora* may easily be confused with some *Streptosporangium* species on morphological grounds, but they are easily differentiated from members of this taxon as they produce motile zoospores, and zoospores have never been detected in *Streptosporangium* strains (Table 8; see The Family Streptosporangiaceae in this Volume). All strains belonging to this taxon produce multispored, usually spherical spore vesicles carried on the aerial mycelium. Nevertheless, it is evident from comparative 16S rRNA gene sequencing and chemical data that spirillosporae belong to the family Thermomonosporaceae (Goodfellow 1989b;

Fig. 6. Two dimensional thin-layer chromatograms of polar lipids: a) *Actinomadura madurae* DSM 43067^T (PL-type I); b) *Microtetraspora glauca* DSM 43311^T (PL-type IV); c) *Thermobifida alba* DSM 43185 (PL-type II); d) *Thermomonospora curvata* DSM 43183^T (PL-type IV); and e) *Microbispora mesophila* DSM 43048^T (PL-type IV). Example for PL-type III, see *Nocardiopsis dassonvillei* (The Family Nocardiopsaceae in this Volume).

Chromatographic conditions: 10 × 10 cm silica-gel-60 thin layer plates were spotted with 20 µl of the extracts from test strains using the procedures of Minnikin et al. (1984); solvent I: chloroform-methanol-water (65:25:4, v/v); solvent II: chloroform-acetic acid-methanol-water (80:15:12:4 v/v). The developed plates were sprayed with 50% sulfuric acid ammonium sulfate and charred at 180°C.

Abbreviations: PG, phosphatidylglycerol; DPG, diphosphatidylglycerol (cardiolipin); PE, phosphatidylethanolamine; OH-PE, hydroxy-PE; PME, phosphatidylmethylethanolamine; NPG, *n*-acetylglucosamine carrying phospholipid (GluNu; Lechevalier et al., 1981); PI, phosphatidylinositol; PIM, PIDM, phosphatidylinositolmannosides; PL, unknown phospholipids; PL, phospholipid types according to Lechevalier et al. (Lechevalier et al., 1977; Lechevalier et al., 1981).

Table 3. Macroscopic and microscopic characters separating species of *Actinocorallia*, *Actinomadura*, *Spirillospora* and *Thermomonospora*.

^aAerial mycelium is usually absent, a sparse white aerial mycelium is produced on corn meal agar (Schäfer, 1973).

Based on data of Vobis and Kothe (1989) and Wink (2002).

Stackebrandt et al., 1997; and Zhang et al., 2001). There are some contradictory results on the phospholipid pattern of *Spirillospora albida*; Lechevalier and coworkers reported a phospholipid pattern I as expected (Lechevalier et al., 1981), whereas Hasegawa and his colleagues found PE in addition to DPG, PG and PI, i.e., a phospholipid pattern II (Hasegawa et al., 1979). The fatty acid profile of *Spirillospora* strains is type 3a sensu Kroppenstedt (Kroppenstedt, 1985).

Spirillospora albida and *S. rubra* produce a substrate mycelium that is usually white, pale yellow, pale buff pink, or red to reddish-brown; the aerial mycelium is white (Couch, 1963; Schäfer, 1973). Spherical to vermiform spore vesicles (5–24 µm in diameter) are formed on the aerial mycelium (Fig. 3). On initiation of “sporangial” development, the ends of aerial hyphae first coil and then wind in branches within a common sheath (Lechevalier et al., 1966; Vobis, 1985a). Small, two-layered cross-walls divide sporangous hyphae into oblong segments that differentiate into spores. The latter, which are rod shaped and curved, are motile by means of one to seven subpolarly inserted flagella. The spore vesicles are considered to be resistant to desiccation. When flooded with

water, zoospores are released from the spore vesicles through a rupture in the envelope or through a large irregular pore (Couch, 1963).

Pathogenicity

The only members of the Thermomonosporaceae known to be pathogenic for humans are *Actinomadura latina*, *A. madurae* and *A. pelletieri*. Members of these taxa cause mycetoma, a chronic suppurative granulomatous disease of subcutaneous tissue and bones that is characterized by swellings, abscesses, and discharge of pus. The pus contains granules; those found in pus infected with *A. madurae* strains are soft, white to yellow or reddish, usually 1–5 mm in diameter, and are spherical or angular with lobes, whereas those characteristic of *A. latina* and *A. pelletieri* infections are hard, deep red, 0.3–0.5 mm in diameter, and usually spherical to oval. Infection usually occurs through skin lesions contaminated with dust, soil or vegetable matter and remains localized with dissemination occurring by direct extension of the organisms through the tissues. As infection becomes increasingly chronic, the lesions extend more deeply into the body with

involvement of both muscle and bone. Animal models of infection with *Actinomadura* have not been developed though Rippon (1968) reported that virulent strains of *A. madurae* produce a collagenase that has a significant role in the pathogenicity of the organism.

Actinomadura pelletieri occurs mainly in Africa whereas *A. madurae* is widespread in all tropical and subtropical areas (Schaal and Beaman, 1984b; Gumaa et al., 1986; Develoux et al., 1988). Colonies resembling members of these species have been isolated from water (Lawson and Davey, 1972). There is evidence that climatic conditions may play a major role in the distribution of mycetomas. In Venezuela, most cases of actinomycetoma have been reported from semi-arid areas colonized by trees and bushes such as *Acacia tortuosa*, *Amarantus espinosus* and *Prosepis fuliflora* and cacti (e.g., *Opuntia caribea* and *Opuntia wentiana*; Serrano et al., 1986). Since the trees and cacti have spines and thorns, it is very common for agricultural workers to puncture their skin. Intensive studies on the occurrence, cause of mycetomas, and epidemiological considerations have been carried out in Yemen (Yu et al., 1993), Sudan (Boiron et al., 1998), and West Bengal, where 264 cases were diagnosed between 1981, and 2000 (Maiti et al., 2002).

Effective treatment of patients with mycetomas requires the identification of the causative agents, as the disease may be caused by members of several actinomycete taxa (e.g., *Nocardia asteroides*, *Nocardia brasiliensis* and *Streptomyces somaliensis* cause actinomycetomas) or by fungi (cause eumycetoma; McNeil and Brown, 1994; Goodfellow, 1997). All types of mycetoma infections should be treated with early surgical debridement and tissue culture. The clinical picture of an actinomycetoma is almost uniform irrespective of the causal agent. In addition to surgical management, these patients should be managed adjunctively with a prolonged course of chemotherapy. The choice of antimicrobial agents for therapy is currently based on non-comparable clinical observations (McNeil and Brown, 1994; Goodfellow, 1997). The most encouraging results have been obtained with sulfonamides. Alternative therapies mainly involve the use of minocycline, penicillin, and tetracycline. *Actinomadura madurae* infections have been successfully treated by resection and prolonged doxycycline chemotherapy (Davis et al., 1999).

The growth of thermophilic actinomycetes in high temperature environments leads to the release of spores that can cause allergic alveolitis. There are currently no grounds for implicating the spores of *Thermomonospora* species in such respiratory disorders (Lacey, 1988) though the cause of mushroom worker's disease, a form of

allergic alveolitis, is still a matter for conjecture. Precipitins to *Faenia rectivirgula* and *Thermoactinomyces* species have been found (Moller et al., 1976) and *Thermoactinomyces dichotomicus* has been implicated (Molina, 1982), but these species have seldom been detected in compost (Lacey, 1973). Conversely, precipitins have not been demonstrated to any of the other actinomycetes tested, including *Thermomonospora chromogena* and *Thermobifida fusca* strains, which are found in high numbers in high temperature habitats. However, antigenic extracts may have been unsatisfactory, given the poor growth of these organisms in culture (Lacey, 1988). Both mesophilic and thermophilic monosporic actinomycetes once described as *Thermomonospora* have been isolated from soil (Krassil'nikov and Agre, 1965; Locci et al., 1967; Nonomura and Ohara, 1971c; Nonomura and Ohara, 1974).

Metabolism and Genetics

Knowledge of the genetics and metabolism of *Actinomadura* strains has increased during the last decade with the discovery that actinomadarae are a rich source of antibiotics (Table 9). Earlier work on such organisms is difficult to interpret owing to the uncertain taxonomic status of the organisms examined. Indeed, without further characterization it is not possible to know whether organisms simply labeled *Actinomadura* are correctly named or belong to the *Actinomadura pusilla* group now classified in the genus *Nonomuraea* (Goodfellow et al., 1988; Zhang et al., 1998).

Nevertheless it is clear that actinomadarae are chemo-organotrophic actinomycetes with an oxidative type of metabolism. Members of most species grow well in the range 25–40°C, but several are thermophilic, with an optimum growth temperature of 50–65°C. Actinomadarae can metabolize a wide range of sugars as sole carbon sources for energy and growth; proteolytic activity is shown by the capacity of most strains to attack casein and gelatin (Goodfellow et al., 1979; Goodfellow and Pirouz, 1982; Athalye et al., 1985; Trujillo and Goodfellow, 1997; Trujillo and Goodfellow, 2003; Quintana et al., 2003). In contrast, neither chitin nor xanthine or xylan is metabolized, but an uncharacterized *Actinomadura* strain has been implicated in the degradation of wheat lignocellulose (McCarthy and Broda, 1984a). Pathogenic strains of *A. madurae* produce collagenolytic enzymes (Rippon, 1968), and *Actinomadura* strain R39 synthesizes serine peptidases (Schindler et al., 1986).

All *Thermomonospora* strains grow within the temperature range 40–48°C and pH range 8.0–9.0. However, strains of *T. curvata* and *T.*

chromogena differ in pH and temperature optimum (Table 7). The most commonly isolated thermomonosporae are thermophiles with a growth temperature range of 40–55°C and an optimum of 50°C. *Thermomonospora* strains have several enzymes in common, including catalase, carboxymethylcellulose, deaminase, β -glucosidase, β -galactosidase and β -xylanase (McCarthy and Cross, 1984b; McCarthy and Cross, 1984c; McCarthy, 1989). Esculin, arbutin, and testosterone are degraded, but chitinase activity is universally absent. All strains attack casein and gelatin, and usually agar, keratin, starch and the Tweens, and apart from *T. curvata*, pectin.

The capacity to degrade cellulosic substrates is an important property of many strains, and *Thermomonospora* cellulases (Crawford and McCoy, 1972; Stutzenberger, 1972b; Hägerdal et al., 1978; Bachmann and McCarthy, 1989; Ball and McCarthy, 1989a) and xylanases (McCarthy et al., 1985) have been partially characterized. Amylases from *Thermomonospora* species, including *T. curvata*, are extremely active and stable at 60–70°C and at slightly acid to neutral pH values (Kuo and Hartman, 1967; Stutzenberger and Carnell, 1977; Lupo and Stutzenberger, 1988). Separation of endoglucanase and exoglucanase activity in culture filtrates of *Thermomonospora curvata* has been described (Stutzenberger, 1972b; Stutzenberger and Lupo, 1986b; Lin and Stutzenberger, 1995).

In *T. curvata*, cellobiose has been reported as both a poor (Fennington et al., 1984) and good (Stutzenberger and Kahler, 1986a) cellulase inducer. One possible explanation for this apparent discrepancy is that the role of cellobiose as an inducer or repressor of cellulase production is concentration-dependent and that the threshold concentrations for induction and repression of cellulase production vary in different strains. In *T. curvata* it has been shown that a sufficient concentration of cellobiose to support rapid growth leads to repression of cellulase biosynthesis (Wood et al., 1984). These cultures also provided evidence implicating cyclic AMP as the mediator of catabolic repression of cellulase biosynthesis in *T. curvata*.

Optimization of cellulase production is usually achieved by empirical manipulation of growth conditions and is often species- or strain-specific (McCarthy, 1987). Cellulose degradation or cellulase production can be improved by altering the cellulose source and nitrogen component employed (Moreira et al., 1981; Fennington et al., 1984). Comparable levels of cellulase activity in *Thermomonospora* strains and the cellulolytic fungus *Trichoderma reesii* (commonly used as the reference standard) have been reported. However, different sources of cellulose can greatly affect the extent of hydrolysis realized

(Stutzenberger, 1979; Ferchak et al., 1980). *Thermomonospora curvata* releases sixteen times more β -glucosidases when grown on protein-extracted lucerne fiber compound compared with growth on cellulose or purified cellulose (Bernier and Stutzenberger, 1988a). Enhanced cellulase production has been achieved by mutation (Meyer and Humphrey, 1982), and in *T. curvata* (Fennington et al., 1984), the mutants have been identified as catabolite repressor-resistant.

Xylanase activity has received comparatively little attention even though it is more widespread than cellulase activity among actinomycetes. This imbalance is being redressed using *Thermomonospora* strains that have been extensively studied in relation to their cellulolytic activity (McCarthy et al., 1985; Ristroph and Humphrey, 1985a; Ristroph and Humphrey, 1985b; Ball and McCarthy, 1989a). The production of xylanases is correlated with the growth stage, and degradation is the result of endoxylanase activity. The pH and temperature relationships of *Thermomonospora* xylanases have much in common with those of the corresponding cellulases (McCarthy, 1987). Similarities include optimal activity within the pH range 5–8, increased thermostability of enzymes from thermophilic strains, and lower temperature optima for all-bound dimer hydrolases. *Thermomonospora* xylanases are sufficiently active to produce some direct saccharification of lignocellulose as shown by the generation of xylose from straw (McCarthy et al., 1985). Xylose inhibition of β -xylosidase has been demonstrated in a *Thermomonospora* strain (Ristroph and Humphrey, 1985b).

The genus *Thermomonospora* also contains lignin-degrading organisms (McCarthy and Broda, 1984a; McCarthy et al., 1986). The latter found that *Microbispora* (*Thermomonospora*) *mesophila* degraded lignocellulose to a water-soluble polymeric complex as the main product. The capacity to solubilize lignin is common among lignocellulose-degrading actinomycetes (Ball et al., 1989b).

Little information is available on the genetics of *Thermomonospora* species. Plasmids have been isolated from *Thermomonospora* isolates (Pidcock et al., 1985) and *T. chromogena* (McCarthy, 1989). Protoplast formation, regeneration and transformation of *Thermobifida fusca* (formerly *Thermomonospora*) with plasmid pIJ702 have also been reported (Pidcock et al., 1985). Plasmids such as pIJ702 (Katz et al., 1983) are now being used routinely for the cloning of antibiotic resistance, catabolic and biosynthetic genes of *Streptomyces*, with the most common gene recipient being *Streptomyces lividans* (Chater and Hopwood, 1984). A gene coding for one of the endoglucanases of *Thermobifida fusca* has been cloned into and expressed

in *Bacillus subtilis*, *Escherichia coli* and *Streptomyces lividans* (Collmer and Wilson, 1983; Ghangas and Wilson, 1987) as a first step towards designing a vehicle for the production of high levels of thermostable cellulases. A number of bacteriophages that infect cellulolytic *Thermomonospora* strains (Lawrence et al., 1986) and members of *Faenia* and *Thermoactinomyces* species (Kurup and Heinzen, 1978) have been characterized.

Molecular genetic studies on *Thermomonospora chromogena* ATCC 43196^T performed by Yap et al. (1999) revealed that the genome of this strain contained small interfering (si) rRNA operons (*rrn*), four of which were complete and two incomplete. Comparative analyses showed that the operon *rrnB* exhibits a high level of sequence variation compared to the other five, which have nearly identical sequences. The coding sequences for the 16S and 23S rRNA genes differ by approximately 6% and 10%, respectively, between the two types of operons. Normal functionality of the *rrnB* gene operon was concluded on the basis of the nonrandom distribution of nucleotide substitutions, the presence of compensation nucleotide covariations, the preservation of secondary and tertiary rRNA structures, and the detection of correctly processed rRNAs in the cell. Comparative sequence analysis also revealed a close evolutionary relationship between the *rrnB* operon of *Thermomonospora chromogena* and the *rrnA* operon of another thermophilic actinomycete, namely *Thermobispora bispora*. These results provide strong evidence that *Thermomonospora chromogena* acquired the *rrnB* operon from *Thermobispora bispora* or related organisms via horizontal gene transfer (Yap et al., 1999). Similar reports on 16S rRNA sequence diversity were reported by Reischl and coworkers for *Mycobacterium celatum* (Reischl et al., 1998) and for the archeon *Halobacterium marismortui* (Mylvaganam and Dennis, 1992). The taxonomic implications of the intraspecific variation (within and between strains) of prokaryotic rRNA sequences were discussed by Clayton and coworkers (Clayton et al., 1995).

Applications

Actinomadura and *Thermomonospora* strains are sources of new antibiotics, enzymes, and products with pharmacological activity. *Actinomadura carminata* produces carminomycin (Gauze et al., 1973), *A. citrea* rifamycin (Gauze et al., 1975), *A. kijaniata* kijanimicin (Waitz et al., 1981), *A. macra* polycyclic ether antibiotics (Huang, 1980), "*A. parvasota*" parvodisin (Christensen et al., 1987), and *A. oligospora*

and *A. yumaensis* polyether antibiotics (Labeda et al., 1985; Mertz and Yao, 1986). In addition, novel antitumor (Takahashi et al., 1988; Matson et al., 1989), glycolipid (Goldstein et al., 1987), nucleoside (Suhadolnik et al., 1989), tetracycline (Patel et al., 1987) and chlorine-containing polyether antibiotics (Cullen et al., 1987) have been isolated from poorly characterized strains labeled *Actinomadura*. An *Actinomadura viridilutea* strain produced a compound that inhibits reverse transcriptase of avian myeloblastosis virus (Sasaki et al., 1988), a mesophilic *Thermomonospora* strain, with a type II phospholipid pattern, produced a novel isochromane-quinone which inhibits thrombin-induced aggregation of human platelets (Patel et al., 1989), an organism labeled "*A. spiculospora*" produced a specific and reversible inhibitor of angiotensin I converting enzyme (Koguchi et al., 1986), and unspecified thermophilic thermomonosporae produced a new naphthoquinone antibiotic (Hedge et al., 1986); further details are given in Table 9.

Some actinomycetes, including *Actinomadura* strain R39, excrete large amounts of DD-carboxypeptidases, enzymes that are generally membrane-bound. When isolated and characterized, DD-carboxypeptidases serve as model enzymes for elucidating the mechanism of β -lactam antibiotic action (Ghuysen et al., 1979). The inactivation of DD-carboxypeptidases from *Actinomadura* strain R39 by β -lactam antibiotics facilitated the development of a rapid and sensitive method for the qualitative determination of these antibiotics in biological fluids such as human serum and cow's milk (Frere et al., 1980; Schindler et al., 1986). *Actinomadura* strains are also a source of novel restriction endonucleases (Roberts, 1984; Kessler et al., 1985). Proteases from *Thermobifida fusca* have been used on an industrial scale (Desai and Dhala, 1969).

DNA fragments which contain the gene that encodes the extracellular lactamases of *Actinomadura* strain R39 have been introduced into *Streptomyces lividans* TK24 via the high-copy number, promoter-probe plasmid pIJ424 (Piron-Fraipont et al., 1989). Maximal levels of β -lactamase secretion were observed with *S. lividans* CM3 harboring the recombinant plasmid pDML150. The DNA segment in pDML150 that encodes the β -lactamase has been sequenced (Houba et al., 1989). The β -lactamase precursor is a 304-amino acid polypeptide, the amino terminal region of which has the characteristic features of a signal peptide. The *Actinomadura* strain R39 β -lactamase is a marker of the class A β -lactamases; it shows a particularly high homology with the β -lactamases of *Bacillus licheniformis*.

Thermophilic monosporic actinomycetes have been evaluated for cellulose bioconversion pro-

cesses designed to produce single cell protein (Bellamy, 1974; Bellamy, 1977; Humphrey et al., 1977; Wood, 1985; Crawford, 1988) or sugar syrups for fermentation to ethanol (Hägerdal et al., 1979; Lee and Humphrey, 1979; Ball and McCarthy, 1988). Several of these publications have referred to a cellulolytic *Thermoactinomyces* strain that has been labeled *T. cellulosa* (Vacca and Bellamy, 1976), but this organism is now known to be a member of the genus *Thermomonospora* (Hägerdal et al., 1980).

Thermobifida fusca and other thermomonosporae have been grown at 55°C on a pilot scale to convert high-cellulose low-lignin pulp mill waste into single cell protein (Crawford et al., 1973). The proteinaceous product had a high nutritional value as a feed supplement in the diet of chicks (Harkin et al., 1974). Thermostable cellulases are also attractive as catalysts in biomass conversion, since their temperature optima can reduce contamination problems in economically feasible nonaseptic applications (Wood, 1985).

A cellulase enhanced *Thermomonospora* mutant grown on chemically pretreated poplar wood was found to use 70% of the woody biomass after 62 h at 55°C but failed to grow well on wood that had not been chemically pretreated. Bellamy (1977) used the parental strain of the same organism, then known as "*Thermoactinomyces cellulosa*," for the bioconversion of chemically pretreated lignocellulosic feedlot waste into microbial biomass. The culture degraded up to 85% of the cellulosic and over 90% of the hemicellulosic fraction of the substrate. The process led to the production of a product with high protein content but was not economical because of the cost of the chemical pretreatment needed to obtain a suitable degradable substrate.

Some success has been achieved in the use of thermophilic actinomycetes in processes designed for the saccharification of purified celluloses. The cellulase complex of *Thermobifida* (*Thermomonospora*) *fusca* YX, the Bellamy organism, readily saccharifies finely ground, acid swollen Avicel, a purified chemically pretreated cellulose (Su and Paulavicius, 1975; Ferchak and Pye, 1980). In subsequent work (Ferchak and Pye, 1983), a process was developed for saccharification of cellulose using a cellulose and cellobiose mixture. In a 7-day, 50°C saccharification, 15–20% glucose syrups were generated from acid swollen Avicel. The availability of cellulase-overproducing strains of *Thermomonospora* species (Fennington et al., 1982; Meyer and Humphrey, 1982) should further improve the commercial potential of saccharification processes.

Ligninolytic *Thermomonospora* strains may have potential for the biological bleaching of

pulps or in biological pulping processes given their capacity to solubilize lignin and separate it from the cellulose component of lignocellulose (McCarthy et al., 1986). It has also been suggested (Crawford, 1988) that the ability of some *Thermomonospora* strains to simultaneously attack all of the major components of lignocellulose (i.e., cellulose, lignin and hemicellulose) may be used to develop direct fermentations for the conversion of lignocellulosic wastes into specific high value chemicals and for single cell protein. The development of efficient industrial size bioreactors for solid substrate fermentations will help to foster commercially successful actinomycete-adapted bioconversion processes.

In a study on the degradation of natural rubber, 1220 bacteria from different culture collections were tested (Jendrossek et al., 1997). The results were unexpected because only actinomycetes were able to degrade natural rubber. Most of the positive strains belonged to the genera *Streptomyces* (31), *Actinoplanes* (3), *Dactylosporangium* (1), *Micromonospora* (5), and *Nocardia* (2), but only one strain, *Actinocorallia libanotica* DSM 44554^T, belonged to the family Thermomonosporaceae. It seems that the degradation of natural rubber is a hallmark of actinomycetes, as all of the rubber-degrading strains from the collections and those that have been isolated from different sources using natural rubber or rubber-containing baits were actinomycetes (Jendrossek et al., 1997; Linos et al., 1999; Linos et al., 2000; Linos et al., 2002; Arenskötter et al., 2000).

The Family Streptosporangiaceae

MICHAEL GOODFELLOW AND ERIKA TERESA QUINTANA

Phylogeny

The founder members of the family Streptosporangiaceae Goodfellow et al. 1990 have a number of taxonomic pedigrees. Couch (1955a) classified the genus *Streptosporangium* in the family “Actinosporangiaceae” together with sporangiate actinomycetes belonging to the genus *Actinoplanes*. This family was renamed Actinoplanaceae by Couch (1955b). In addition to *Actinoplanes* (the type genus) and *Streptosporangium*, this taxon encompassed the genera *Amorphosporangium*, *Ampullariella*, *Dactylosporangium*, *Kitasatoa*, *Pilimelia*, *Planobispora*, *Planomonospora* and *Spirillospora* (Couch and Bland, 1974). Members of all of these genera were considered to form sporangia.

Representatives of the genera *Planobispora*, *Planomonospora*, *Spirillospora* and *Streptosporangium* were subsequently shown to form a DNA homology group that was readily separated from a second aggregate DNA relatedness group which encompassed the genera *Actinoplanes*, *Ampullariella* and *Dactylosporangium* (Farina and Bradley, 1970). Organisms in the first group contained *meso*-diaminopimelic acid (*meso*-A₂pm) and the sugar madurose (wall chemotype III/B sensu Lechevalier and Lechevalier, 1970b, Lechevalier and Lechevalier, 1970c) whereas those in the second taxon had a wall chemotype II, that is, they contained *meso*- or hydroxy-A₂pm or both and glycine (Lechevalier and Lechevalier, 1970b).

The genera *Actinoplanes*, *Dactylosporangium*, *Micromonospora* and *Pilimelia* are now known to have many properties in common and are classified in the family Micromonosporaceae (Krassil'nikov, 1938) emended Stackebrandt et al. 1997. The genus *Kitasatoa* has become a subjective synonym of the genus *Streptomyces* (Goodfellow et al., 1986), the genera *Amorphosporangium* and *Ampullariella* have been reduced to subjective synonyms of the genus *Actinoplanes* (Stackebrandt and Kroppenstedt, 1987), and the genus *Spirillospora* is now classified in the family Thermomonosporaceae (Zhang et al., 2001).

The oligosporic genera (*Actinomadura* Lechevalier and Lechevalier 1970b, *Microbispora* Nonomura and Ohara 1957, and *Microtetraspora* Thiemann et al. 1968b) and the sporangiate genera (*Planobispora* Thiemann and Beretta 1968a, *Planomonospora* Thiemann et al. 1967, *Spirillospora* Couch 1963, and *Streptosporangium* Couch 1955a) belong to an aggregate group, the maduromycetes (Goodfellow and Cross, 1984; Goodfellow, 1989a; Goodfellow, 1989b). Apart from representatives of the genus *Spirillospora*, these taxa formed a recognizable suprageneric group on the basis of 16S rRNA gene cataloguing and sequencing data (Stackebrandt, 1986).

The taxonomic status of the genera assigned to the maduromycetes was formalized by the proposal that *Streptosporangium* be recognized as the type genus of a new suprageneric taxon, the family Streptosporangiaceae Goodfellow et al. 1990. This family also served as a taxonomic niche for the genera *Microbispora*, *Microtetraspora* (including the *Actinomadura pusilla* group sensu Kroppenstedt et al. [1990]), *Planobispora*, *Planomonospora*, and initially for the genus *Spirillospora*. Additional genera have been added to the family, namely *Acrocarpospora* Tamura et al. 2000, *Herbidospora* Kudo et al. 1993, *Planotetraspora* Runmao et al. 1993, and *Nonomuraea* Zhang et al. 1998. In general, representatives of the nine genera classified in the family Streptosporangiaceae form distinct, but related, taxa on the basis of 16S rRNA gene sequence data (Fig. 1).

The family Streptosporangiaceae (Goodfellow et al. 1990) emended Ward-Rainey et al. 1997 encompasses aerobic, Gram-positive, non-acid-alcohol-fast, chemoorganotrophic actinomycetes that form a branched, nonfragmenting substrate mycelium. When formed, aerial hyphae differentiate into either short chains of arthrospores or spore vesicles containing one to many motile or nonmotile spores. In the absence of aerial hyphae, sporophores are borne on the substrate mycelium. Members of the family typically contain *meso*-A₂pm in a wall peptidoglycan that contains madurose as the diagnostic sugar, have an A1γ type peptidoglycan, *N*-acetylated muramic

Fig. 1. Neighbor-joining tree based on nearly complete 16S rRNA gene sequences showing positions of representative strains classified in the family Streptosporangiaceae. Asterisks indicate branches of the tree that were also found using the least-squares, maximum-likelihood and maximum-parsimony tree-making algorithms. The numbers at the nodes indicate the levels of bootstrap support (%) based on a neighbor-joining analysis of 1000 re-sampled datasets; only values above 50% are given. The bar indicates 0.1 substitutions per nucleotide position. ^T, type strain. Type species are in bold. It has been proposed that the type strain of *Streptosporangium claviforme* be reduced to a synonym of *Herbidospira cretacea*, though this proposition needs to be checked.

acid, and major amounts of glucosamine-containing polar lipids. The cellular fatty acids include straight, *iso*- and *anteiso*-branched and 10-methyl acids. Most of the unsaturated, di- and tetrahydrogenated menaquinones have 9 or 10 isoprene units. The G+C content of the DNA lies within the range of 64–73 mol%. The type genus is *Streptosporangium* Couch 1955a^{AL}.

Members of the family Streptosporangiaceae are chemically homogeneous but morphologically diverse (Table 1). However, strains that bear spore vesicles (*Acrocarpospora*, *Planobispora*, *Planomonospora*, *Planotetraspora* and *Streptosporangium*) are closely related to organisms that carry one or more spores in spore chains (*Herbidospira*, *Microbispora*, *Microtetraspora* and *Nonomuraea*). Each spore vesicle contains a coiled chain of arthrospores formed by septation of an unbranched, spiral hypha

within an expanded sporangiophore sheath (Vobis and Kothe, 1985b). Spore formation is not endogenous, and hence the term “spore vesicle” has greater precision than does the original term “sporangium” (Cross, 1970; Sharples et al., 1974). Studies on spore maturation have shown that spores in spore vesicles and spore chains are formed in essentially the same way. In each case, spores are differentiated by fragmentation of a hypha within its sheath, and the latter either expands to form the vesicular envelope or remains around the spore chain (Lechevalier et al., 1966; Sharples et al., 1974; Vobis and Kothe, 1985b).

Streptosporangium Couch 1955a, 148^{AL}

This taxon was proposed for sporangiate actinomycetes that formed nonmotile sporangiospores on abundant aerial hyphae. Initially, one species, *Streptosporangium roseum*, was rec-

Table 2. Validly described species and subspecies of the genus *Streptosporangium*.

^aKudo et al. (1993) considered this organism to be a subjective synonym of *Herbidospira cretacea*.

ognized but others were soon added (Table 2). The genus was shown to be heterogeneous on the basis of spore and spore vesicular morphology (Nonomura, 1989c), electrophoretic mobility of ribosomal protein AT-L30 (Ochi and Miyadoh, 1992), 16S rRNA (Kemmerling et al., 1993) and 5S rRNA (Kudo et al., 1993) gene sequences, and discontinuous distribution of chemical markers (Stackebrandt et al., 1994).

Stackebrandt and his colleagues found that streptosporangiae had many chemical properties in common but could be assigned to two groups on the basis of chemical differences. Members of most species, including *S. roseum*, had a phospholipid pattern type IV and predominant proportions of MK-9 [H₂, H₄, H₆], whereas strains in the second group, which contained *S. albidum* and *S. viridigriseum*, had a MK-9 [H₄] as the predominant isoprenologue and a phospholipid pattern type II; these results were in excellent agreement with corresponding 16S rRNA gene sequence data (Kemmerling et al., 1993). Stackebrandt and his colleagues proposed that *Streptosporangium albidum* Fumurai et al. 1968, *Streptosporangium viridigriseum* subsp. *kofuense* Nonomura and Ohara 1969b, and *Streptosporangium viridigriseum* subsp. *viridigriseum* Okuda et al. 1966 be assigned to a new taxon, the genus *Kutzneria*, as *Kutzneria albidum* comb. nov., *Kutzneria viridigrisea* comb. nov., and *Kutzneria kofuensis* comb. nov., respectively.

Streptosporangiae characteristically form aerial hyphae that carry, on either short or long sporophores, single or clustered spore vesicles that may be up to 40 µm in diameter (Figs. 2 and 3). They have a wall chemotype III (Lechevalier and Lechevalier, 1970b), that is, *meso*-A₂pm in

Fig. 2. *Streptosporangium album* CBS 426.61^T on oatmeal agar. Scanning electron microscopy, gold splattered. Sporangiophores are short. From Nonomura (1989c), with permission.

a wall peptidoglycan that lacks characteristic sugars other than madurose (3-*O*-methyl-D-galactose; Lechevalier and Gerber, 1970a) and a peptidoglycan of the A1γ type (Schleifer and Kandler, 1972). Members of the taxon are rich in *iso*-, *anteiso*-, saturated, unsaturated, and methyl-branched fatty acids (pattern 3c; Kroppenstedt, 1985; Kudo et al., 1993; Whitham et al., 1993; Stackebrandt et al., 1994), contain di- and tetrahydrogenated menaquinones with nine isoprene units as predominant isoprenologues (Kroppenstedt, 1985; Kudo et al., 1993; Whitham et al., 1993; Stackebrandt et al., 1994), and have phospholipid patterns characterized by glucosamine-containing lipids with phosphatidylethanolamine, diphosphatidylglycerol and phosphatidylinositol (Lechevalier et al., 1977; Lechevalier et al., 1981b; Kudo et al., 1993;

Fig. 3. *Streptosporangium album*. Scanning electron microscopy, gold splattered. Sporangial walls (membranes) are thin. From Nonomura (1989c), with permission.

Whitham et al., 1993; Stackebrandt et al., 1994). The G+C content of the DNA is 69–71 mol% (Tsyganov et al., 1966; Yamaguichi, 1967; Farina and Bradley, 1970; Stackebrandt et al., 1994). Type species: *Streptosporangium roseum* Couch 1955a, 151^{AL}. Type strain: ATCC 12428^T=DSM 43021^T.

Acrocarpospora Tamura et al. 2000, 1170^{AL}

This aerobic, Gram-positive, non-acid-alcohol-fast, nonmotile actinomycete forms a stable, branched substrate mycelium. Spherical and club-shaped structures, which contain coiled chains of smooth-surfaced, oval or rod-like spores (0.6–0.8–1.0 µm in diameter), are carried on the tips of aerial hyphae. The organism grows well on oatmeal agar and at 20–30°C. White aerial hyphae and pale yellow substrate mycelium, but no diffusible pigments, are formed on most standard growth media. Cell walls contain alanine, glutamic acid and *meso*-A₂pm and *N*-acetylated muramic acid. The peptidoglycan is of the A1γ type. Strains contain di- and tetrahydrogenated menaquinones with nine isoprene units as predominant isoprenologues; glucose and madurose as major sugars; phosphatidylethanolamine as the diagnostic phospholipid; and *iso*-C_{16:0}, 10-methyl C_{17:0}, C_{17:0} and C₁₇ as major fatty acids, but lack mycolic acids. The G+C content of the DNA is 68–69 mol%. Type species: *Acrocarpospora pleiomorpha* Tamura et al. 2000, 1170^{AL}. Type strain: DSM 44706^T=NBRC 16267^T.

In addition to the type species, there are two additional species, *A. corrugata* and *A. macrocephala*. The former was originally classified as *Streptosporangium corrugatum* (Williams and Sharples, 1976). From the 16S rRNA Streptosporangiaceae gene tree (Fig. 1), the representatives of the *Acrocarpospora* species are apparently closely related to one another and to the type strains of *Herbidospora cretacea*, *Planotetraspora mira* and *Planotetraspora silvatica*. However, the *Acrocarpospora* strains

can be distinguished from *Herbidospora cretacea* (including the type strain of *S. claviforme*) using morphological and menaquinone data and from the genus *Planotetraspora* using morphological properties and whole-organism sugar composition.

Herbidospora Kudo et al. 1993, 319^{AL}

This aerobic mesophilic actinomycete forms a stable, branched substrate mycelium, but does not produce true aerial hyphae. Straight chains of nonmotile, smooth-surfaced spores (10–30 per chain) are borne at tips of sporophores branching in clusters from the vegetative mycelia. The substrate mycelia are yellow to brown on most media; distinctive exopigments are not formed. When sporulation occurs, the surface of the colony is white or brownish yellow. Thiamine is required for growth. The organism is susceptible to lysozyme. Cell walls contain *meso*-A₂pm and acetylated muramic acid but lack significant amounts of glycine. Whole-organism hydrolysates contain glucose, mannose, ribose, and a trace of madurose. Strains contain major amounts of *iso*-hexadecanoic, *n*-hexadecanoic, *n*-heptadecanoic, 10-methylheptadecanoic, and 2-hydroxy acids; phosphatidylethanolamine and glucosamine-containing phospholipids as diagnostic polar lipids; and major proportions of tetrahydrogenated menaquinones with ten isoprene units with hydrogenation at units III and IX (MK-10 [III, IX-H₄]), but lack mycolic acids. The G+C content of the DNA is 69–71 mol%. Type species: *Herbidospora cretacea* Kudo et al. 1993. Type strain: DSM 44071^T=JCM 8553^T.

The type strains of *Herbidospora cretacea* Kudo et al. 1993 and *Streptosporangium claviforme* Petrolini et al. 1993 belong to the same genomic species and share key morphological features—similarities which led Kudo and his colleagues to propose that the latter be seen as a subjective synonym of the former. However, apparent from the 16S rRNA Streptosporangiaceae gene tree is that the two strains form distinct albeit related phyletic lines (Fig. 1).

Microbispora Nonomura and Ohara 1957, 307^{AL}

This taxon was proposed for actinomycetes that form conspicuous aerial hyphae bearing longitudinal pairs of spores. It currently contains ten validly described species, excluding *Microbispora echinospora* Nonomura and Ohara 1971b and *Microbispora viridis* Miyadoh et al. 1985, which have been reclassified as *Actinomadura rugatobispora* (Miyadoh et al., 1985) Miyadoh et al., 1990 and *Actinomadura viridis* (Miyadoh et al., 1985) Miyadoh et al. 1990, respectively. *Microbispora bispora* (Lechevalier, 1965), which was originally described as *Thermopolyspora bispora* (Henssen, 1957), has been transferred to a new genus, *Thermobispora*, as

Thermobispora bispora (Henssen, 1957; Wang et al., 1996; and see The Family Thermomonosporaceae in this Volume). In contrast, *Thermomonospora mesophilica* Nonomura and Ohara 1971b, which forms single spores, has been reclassified as *Microbispora mesophila* (Nonomura and Ohara, 1971b; Zhang et al., 1998).

Miyadoh et al. (1990) undertook a radical revision of the genus *Microbispora* in which they proposed that *M. amethystogenes*, *M. chromogenes*, *M. diastatica*, *M. indica*, *M. karnatakensis* and *M. rosea* be assigned to a single taxon as *M. rosea* subsp. *rosea* and that *M. aerata*, *M. thermodiastatica* and *M. thermorosea* be combined and recognized as *M. rosea* subsp. *aerata*. These proposals were based on DNA:DNA relatedness data, though it was acknowledged that most of the cut-off points used in the circumscription of the two taxa were below the 70% guideline recommended for the delineation of genomic species (Wayne et al., 1987). However, *M. indica* ATCC 35926^T shared 83% DNA relatedness with *M. rosea* JCM 3006^T; the corresponding figure between the type strains of *M. diastatica* and *M. karnatakensis* was 91%. *Microbispora* species form a relatively distinct monophyletic group in the 16S rRNA Streptosporangiaceae gene tree, with most of the type strains forming distinct phyletic lines (Fig. 1). From the 16S rRNA gene tree, the taxon is apparently closely related to the genus *Microtetraspora*, an association supported by all of the tree-making algorithms and 100% bootstrap value in the neighbor-joining tree.

Microbisporae are aerobic, Gram-positive, nonmotile actinomycetes which typically form a conspicuous aerial mycelium bearing longitudinal pairs of spores (Fig. 4) that may be closely arranged along the aerial hyphae, giving the appearance of catkins; spores are not usually formed on the substrate mycelium. In some

cases, the spores are borne at longer intervals (Fig. 5). They first appear as club-shaped initials that later become transformed into the paired spores visible under the light microscope. Spores are either sessile or on short sporophores, spherical to oval (usually 1.2–1.6 µm in diameter) with smooth surfaces. Mature spores are easily detached from the sporophores and each other when placed in water. B vitamins, particularly thiamine, are essential for growth on synthetic media.

Mesophilic and thermophilic species have been described. Mesophilic strains generally produce a pale yellow to distinct pink aerial spore mass, and the reverse side of the colonies is yellowish-brown to orange. Thermophilic strains form a white or pale yellowish-brown to pale pinkish-brown aerial spore mass; the reverse side of colonies is either pale yellowish-brown or yellow brown. Cell walls contain *N*-acetylated muramic acid and major amounts of *meso*-A₂pm but no characteristic sugars. Madurose is present in whole-organism hydrolysates. The organism contains tetrahydrogenated menaquinone with nine isoprene units as the predominant isoprenologue, phosphatidylcholine, and unknown glucosamine-containing components (such as diagnostic polar lipids, tuberculostearic acid and its analogues), but not mycolic acids. The G+C content of the DNA is 71–73 mol%. Type species: *Microbispora rosea* Nonomura and Ohara 1957, 307^{AL}. Type strain: DSM 43839^T=JCM 3006^T.

Microtetraspora Thiemann et al. 1968b, 296^{AL}

This genus was proposed for actinomycetes that form short, sparsely branched aerial hyphae bearing chains of four spores (Fig. 6). This morphological trait was considered typical of the genus though chains of two or three spores, and more rarely five spores, have been reported. Initially, four species were recognized, *Micro-*

tetraspora glauca, the type species, *M. fusca*, *M. niveoalba* and *M. viridis*; the latter has been reclassified as *Actinomadura viridis* (Nonomura and Ohara, 1971a; Miyadoh et al., 1989). The taxon provided a temporary refuge for the *Actinomadura pusilla* group (Fischer et al., 1983; Poschner et al., 1985; Goodfellow et al., 1988; Kroppenstedt et al., 1990) until it became clear that members of this taxon and the three bona fide *Microtetraspora* species mentioned above can be distinguished using numerical taxonomic (Athalye et al., 1985), electrophoretic mobility of ribosomal AT-L30 protein (Ochi et al., 1991; Ochi et al., 1993), and 16S rRNA gene sequence (Wang et al., 1998) data. The *A. pusilla* group was subsequently classified in a new taxon, the genus *Nonomuraea* Zhang et al. 1998. "*Microtetraspora tyrrkensis*" was proposed by Tomita et al. (1991) for an organism that formed hooked or spiral spore chains and other properties consistent with its assignment to the *A. pusilla* group. This organism probably belongs to the genus *Nonomuraea*, though the type strain is no longer available to test this proposition. An additional species, *M. malaysiensis*, has been described for strains isolated from a primary dipterocarp forest soil (Nakajima et al., 2003).

Microtetrasporae are aerobic, Gram-positive, non-acid-alcohol-fast, mesophilic, nonmotile actinomycetes which form stable, highly branched substrate and aerial mycelia. Spore chains, typically containing four spores, are borne exclusively on short aerial hyphae. Spores are spherical (1.2–1.5 µm in diameter) or oval to short cylindrical (1.0–1.4 to 1.2–1.7 µm in diameter) and have smooth surfaces. Some species require B vitamins for growth. The organism is chemoorganotrophic, having an oxidative type of metabolism. It grows well at 20–37°C. Cell walls contain *N*-acetylated muramic acid and major amounts of *meso*-A₂pm but no character-

istic sugars. Madurose is present in whole-organism hydrolysates. The organism contains major proportions of menaquinone with nine isoprene units with hydrogenation at units III and IV (MK-9 [III, IV-[H₄]]); phosphatidylcholine and unknown glucosamine-containing lipids are the major polar lipids. The G+C content of the DNA is 69–71 mol%. Type species: *Microtetraspora glauca* Thiemann et al. 1968b, 296^{AL}. Type strain: ATCC 23057^T=DSM 43311^T.

Nonomuraea Zhang et al. 1998, 419^{AL}

This taxon was introduced to accommodate the species assigned to the *Microtetraspora pusilla* group (Fischer et al., 1983; Poschner et al., 1985; Goodfellow et al., 1988; Kroppenstedt et al., 1990). The genus encompasses aerobic, Gram-positive, non-acid-alcohol-fast strains that form extensively branched substrate and aerial hyphae. The latter bear chains of spores that may be hooked, spiral, straight, or enmeshed in pseudovesicles. Spore surfaces may be folded, irregular, smooth or warty. The growth temperature range is 20–45°C, and some strains grow up to 55°C. Cell walls contain *meso*-A₂pm, and madurose is present in whole-organism hydrolysates (cell wall type III/B sensu Lechevalier and Lechevalier, 1970b). The predominant menaquinones are MK-9 [H₀, H₂, H₄], the phospholipid pattern is characterized by glucosamine-containing lipids with phosphatidylethanolamine variable, phosphatidylmethylethanolamine, diphosphatidylglycerol and phosphatidylinositol (phospholipid type IV sensu Lechevalier et al., 1977), and the predominant fatty acids are 10-methyl-17- and *iso*-16-branched components (pattern 3c; Kroppenstedt, 1985). The G+C content of the DNA is 64–69 mol%. Type species: *Nonomuraea pusilla* Zhang et al. 1998, 419^{AL}. Type strain: ATCC 27296^T=DSM 43357^T.

The genus *Nonomuraea* contains eighteen validly described species, namely *N. africana* (Preobrazhenskaya and Sveshnikova, 1974) Zhang et al. 1998, *N. angiospora* (Zhukova et al., 1968) Zhang et al. 1998, *N. dietziae* Stackebrandt et al. 2001, *N. fastidiosa* (Soina et al., 1975) Zhang et al. 1998, *N. ferruginea* (Meyer, 1981) Zhang et al. 1998, *N. flexuosa* (Meyer, 1989) Zhang et al. 1998, *N. helvata* (Nonomura and Ohara, 1971c) Zhang et al. 1998, *N. longicatena* (Chiba et al., 1999) Zhang et al. 1998, *N. polychroma* (Galanenko et al., 1987) Zhang et al. 1998, *N. pusilla* (Nonomura and Ohara, 1971c) Zhang et al. 1998, *N. recticatena* (Gauze et al., 1984) Zhang et al. 1998, *N. roseola* (Lavrova and Preobrazhenskaya, 1975) Zhang et al. 1998, *N. roseoviolacea* subsp. *carminata* (Gauze et al., 1973) Gyobu and Miyadoh 2001, *N. roseoviolacea* subsp. *roseoviolacea* (Nonomura and Ohara, 1971c) Zhang et al. 1998, *N. rubra* (Sveshnikova et al., 1969) Zhang et al. 1998, *N. salmonea* (Preobrazhenskaya

et al., 1975) Zhang et al. 1998, *N. spiralis* (Meyer, 1981) Zhang et al. 1998, *N. terrinata* Quintana et al. 2003, and *N. turkmeniaca* (Terekhova et al., 1987) Zhang et al. 1998. Representatives of each of these validly described species form a distinct phyletic line in the 16S rRNA Streptosporangiaceae gene tree (Fig. 1).

Planobispora Thiemann and Beretta 1968a, 157^{AL}

This taxon encompasses aerobic, Gram-positive, non-acid-alcohol-fast, chemoorganotrophic actinomycetes that form irregular branched, occasionally septate, substrate hyphae (0.5–1.0 µm in diameter) and sparsely branched, rarely septate aerial hyphae (1 µm in diameter). Cylindrical to clavate spore vesicles (1.0–1.2 µm wide, 6.0–8.0 µm long), each containing a longitudinal pair of spores, are formed singly or in bundles on short ramifications of the aerial hyphae. Spores are straight or slightly curved with rounded ends (1.0–1.2 µm in length) and are motile by means of peritrichous flagella. The spores are pushed out of opposite ends of the spore vesicle, which is easily detached from the supporting hyphae; only a small percentage of spores show motility. They are only motile after being dispersed for some time and usually germinate with one or two polar germ tubes.

Still unclear is whether spores are formed endogenously (Williams and Wellington, 1980) or by simple transformation of sporangeous hyphae (Bland and Couch, 1981). A transverse septum or diaphragm connected to the vesicular envelope divides the two spores (Thiemann, 1970; Vobis and Kothe, 1985b; Fig. 7). The vesicular envelope is smooth and contains fibrillar elements (Vobis and Kothe, 1985b) that resemble those present in *Planomonospora* (Sharples et al., 1974). The type strains of *P. longispora* and *P. rosea* have many phenotypic properties in common; some of these distinguish them from other sporoactinomycetes with a wall chemotype III (Goodfellow and Pirouz, 1982).

The substrate mycelium of planobisporae is either without distinctive color or rose-colored. The aerial mycelium, which develops only on certain agar media, is white or has a light rose tinge. Good growth occurs at pH 6.0–9.0 and temperature 28–40°C but not 20°C or 45°C. Cell walls contain *meso*-A₂pm; madurose is the characteristic whole-organism sugar. Planobisporae contain diphosphatidylglycerol, phosphatidylethanolamine and unknown glucosamine-containing phospholipids as diagnostic polar lipids; major amounts of straight chain, unsaturated, *iso*- and 10-methyl branched fatty acids, and tetrahydrogenated menaquinone with nine isoprene units (MK-9 [III, IV-H₄]) as the predominant isoprenologue. The G+C content of the DNA is 70–71 mol%. Type species: *Plano-*

Fig. 7. Spore vesicle of *Planobispora rosea* strain MB-SE-893. Negative stained: transmission electron micrograph. A diaphragm (da) is visible between the two spores and the longitudinal fibrillar elements in the sporangial envelope. From Vobis (1989a), with permission.

bispora longispora Thiemann and Beretta 1968a, 157^{AL}. Type strain: DSM 43041^T=JCM 3092^T.

The genus contains an additional species, namely, *Planobispora rosea* Thiemann 1970.

Planomonospora Thiemann et al. 1967, 29^{AL}

This taxon was proposed for actinomycetes that form cylindrical or clavate spore vesicles, each containing a single spore, on aerial hyphae. In *Planomonospora parontospora*, the type species, the spore vesicles are sessile and occur in double parallel rows on curved sporangiophores (Fig. 8). A single sporangiophore can bear up to 60 spore vesicles. In the other founder member of the taxon, *P. venezuelensis*, the spore vesicles are developed singly or in groups on short lateral branches (Fig. 9) forming a characteristic palm leaf pattern (Thiemann, 1970). The spores may be formed endogenously (Sharples et al., 1974), but in the *P. parontospora* spore vesicle, development begins with the growth of a sporangeous hypha inside a thin expanding sheath (Vobis, 1985a; Vobis and Kothe, 1985b). Through thickening, the sheath becomes a massive vesicular envelope. The spores, which are released through apical pores, become motile by peritrichous flagella about 30 min after being expelled. They remain motile for up to a day during which time spore germination may begin (Thiemann, 1970). The type strains of *P. parontospora* and *P. venezuelensis* were assigned to a distinct cluster in an

Fig. 8. *Planomonospora parontospora* ATCC 23863^T. Scanning electron microscopy. Numerous monosporous spore vesicles in double parallel rows, arranged directly on bent aerial hyphae. The strain was cultivated for 10 days on soil agar. From Vobis (1989a), with permission.

Fig. 9. *Planomonospora venezuelensis* ATCC 23865^T. Scanning electron microscopy. Monosporous spore vesicles on aerial hyphae in young stages of formation of palm leaf pattern. Cultivation as in Fig. 8. From Vobis (1989b), with permission.

extensive numerical taxonomic analysis of sporo-actinomycetes with a wall chemotype III (Goodfellow and Pirouz, 1982).

The genus *Planomonospora* contains five validly described taxa, namely, *Planomonospora alba* Mertz 1994, *Planomonospora parontospora* subsp. *antibiotica* Thiemann et al. 1967, *Planomonospora parontospora* subsp. *parontospora* Thiemann 1967, *Planomonospora sphaerica* Mertz 1994 and *Planomonospora venezuelensis* Thiemann 1970. The type strains of *P. alba* and *P. sphaerica* form spore vesicles in long parallel rows, which resemble rows of bananas (Mertz, 1994). *Planomonospora sphaerica* strains form large spherical bodies when grown on inorganic

salt starch agar (ISP medium 4; Shirling and Gottlieb, 1966).

Planomonosporae are aerobic, Gram-positive, non-acid-alcohol-fast, chemoorganotrophic actinomycetes that form branched, occasionally septate, nonfragmenting substrate hyphae (0.6–1.0 μm in diameter) and sparsely branched rarely septate aerial hyphae (0.5–1.0 μm in diameter). Cylindrical to clavate spore vesicles (1.0–1.5 μm wide, 3.5–5.5 μm long), each containing a single spore, are formed on the aerial mycelium. Spores are fusiform or cylindrical to clavate and motile by peritrichous flagella; they are 1.0–1.6 μm in diameter and 3.5–5.4 μm in length. Colonies are flat or elevated with smooth surfaces, occasionally wrinkled or slightly crustose. Substrate mycelia show a range of colors, including light orange, brown violet to light brown, and grayish yellow. Aerial mycelia are white with a rose tinge, grayish white or pink. Growth occurs at 20–50°C.

Cell walls contain *meso*-A₂pm. Variation is found in menaquinone, sugar and polar lipid composition. *Planomonospora alba* and *P. sphaerica* strains contain diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphatidylethanolamine, hydroxyphosphatidylethanolamine and glucosamine-containing phospholipids and galactose, madurose and xylose as whole-organism sugars (Mertz, 1994). In contrast, *Planomonospora parontospora* and *P. venezuelensis* have madurose as the characteristic sugar (Kroppenstedt and Kutzner, 1978); the diagnostic phospholipids of *P. parontospora* consist of diphosphatidylglycerol, lysophosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol and unknown glucosamine-containing phospholipids (Hasegawa et al., 1979). Di- and tetrahydrogenated menaquinones with nine isoprene units are the major component in *P. parontospora* whereas tetrahydrogenated menaquinones with eight isoprene units predominate in *P. venezuelensis* (Collins et al., 1984); the major component of *P. alba* and *P. sphaerica* is dehydrogenated menaquinone with nine isoprene units (Mertz, 1994). *Planomonosporae* have complex mixtures of straight chains, unsaturated and branched fatty acids but lack mycolic acids. The G+C content of the DNA is 72 mol%. Type species: *Planomonospora parontospora* Thiemann et al. 1967. Type strain: ATCC 23863^T=DSM 43177^T.

Planotetraspora Runmao et al. 1993, 468^{VP}

The genus *Planotetraspora* was proposed for an isolate that formed long cylindrical spore vesicles that contained four spores in a single row at the ends of short sporangiophores on aerial hyphae. The organism, *Planotetraspora mira*, was reported to contain *meso*-A₂pm in the cell wall and arabinose, galactose, mannose, ribose and

xylose in whole-organism hydrolysates. However, Kudo (2001) found that the strain contained madurose and rhamnose, but not arabinose or xylose in whole-organism hydrolysates. They also noted that it contained tetrahydrogenated menaquinone with nine isoprene units as the predominant isoprenologue and had a type IV phospholipids pattern. Stackebrandt et al. (1997) classified the genus in the family Streptosporangiaceae. A second species, *P. silvatica*, has been described for a strain isolated from a soil sample collected on Amami Island, Japan (Tamura and Sakane, 2004).

Planotetrasporae are aerobic, Gram-positive, non-acid-fast actinomycetes which form moderate, irregularly branching, stable substrate hyphae (0.3–6.0 µm width) and sparsely branched, rarely septate aerial hyphae (0.2–0.4 µm in diameter). Long cylindrical spore vesicles are formed at the ends of short sporophores on aerial hyphae, with each spore vesicle (size about 2.1–2.7 µm 0.6–0.9 µm) containing four spores in a single row. Spores are short, cylindrical, short rod-like or oval elements (0.4–1.4 µm, 0.8–1.5 µm) and may exhibit mobility. They are released and become motile by means of single polar flagella when spore vesicles are immersed in water; active movement of the spores begins 30 min after they are released. In general, the vegetative mycelia are pale yellow to white. Good growth occurs at 25–30°C. Cell walls contain alanine, glutamic acid and meso-A₂pm and N-acetylmuramic acid. Galactose, glucose, madurose, 3-O-methylmannose and rhamnose are found in whole-organism hydrolysates. The predominant isoprenologue is tetrahydrogenated menaquinone with nine isoprene units, phosphatidylethanolamine is the diagnostic phospholipid, and 10-methylated C_{18:0} is the major cellular fatty acid. The G+C content of the DNA is 71 mol%.

Type species: *Planotetraspora mira* Runmao et al. 1993, 468^{AL}. Type strain: DSM 44359^T=JCM 9131^T.

Habitats

Members of the family Streptosporangiaceae are usually associated with soil, but little is known about their role within this milieu. However, improvements in selective isolation procedures are beginning to cast light on the occurrence, distribution, numbers and activity of actinomycete taxa in natural habitats (Suzuki et al., 2001a; Suzuki et al., 2001b). Members of the family Streptosporangiaceae are probably involved in the primary decomposition of plant material in soils.

Streptosporangiae were associated with leaf litter (Van Brummelen and Went, 1957;

Potekhina, 1965), as well as soil and dung (Nonomura and Ohara, 1969a) until the introduction of a selective isolation procedure (Nonomura and Ohara, 1969a) showed that these organisms were an integral part of the actinomycete community in soils. The number of streptosporangiae in various soils in Japan has been estimated at 10⁴ to 10⁶ colony forming units (cfu) per gram dry weight of soil (Nonomura and Ohara, 1969a; Nonomura, 1984). Slightly acid, humus-rich garden soils are a favorite habitat. They have also been isolated from lake sediments (Willoughby, 1969a; Johnstone and Cross, 1976), beach sand (Williams and Sharples, 1976), and pasture and woodland soils (Whitham et al., 1993), but organisms labeled *Streptosporangium* type I from stream water (Willoughby, 1969b), given their morphological properties and capacity to form motile spores, probably belong to the genus *Actinoplanes*. “*Streptosporangium bovinum*” was isolated from infected bovine hooves (Chaves Batista et al., 1963).

Few *Acrocarpospora* and *Herbidospira* strains have been isolated; hence little is known about their distribution in natural habitats. The single representatives of *A. corrugata*, *A. macrocephala* and *A. pleiomorpha* were isolated from beach sand (pH 7.8) at Freshfield, Lancashire, United Kingdom (Williams and Sharples, 1976) and from soil samples collected from Saitama Prefecture, Japan (Tamura et al., 2000), and in Louisiana, United States (Tamura et al., 2000), respectively. Similarly, *Herbidospira cretacea* strains have been isolated from soil and plant material collected from several locations in Japan (Kudo et al., 1993).

Microbispora strains are common in soils. Using selective isolation procedures, counts of between 10⁴ and 10⁶ cfu per gram dry weight of soil have been reported from various Japanese soils (Nonomura and Ohara, 1971b). Larger populations have been found in slightly acidic (pH 5–6), humus-rich garden soils (Nonomura and Ohara, 1969a; Nonomura and Hayakawa, 1988). Microbisporae have also been isolated from marine sediments (Weyland, 1969). *Microbispora corallina* strains were isolated from soil samples collected in a deciduous dipterocarp forest in Thailand (Nakajima et al., 1999). One species, *Microbispora rosea*, has been implicated in a case of pericarditis and pleuritis in a human (Louria and Gordon, 1960). Most of the species previously assigned to the *Actinomadura pusilla* group, and now part of the genus *Nonomuraea*, originated from soil (Nonomura and Ohara, 1971c; Meyer, 1979; Galatenko et al., 1981).

Microtetrasporae are common in soil, notably forest soils (Thiemann et al., 1968b; Nonomura and Ohara, 1971b; Hayakawa et al., 1988; Nakajima et al., 2003). Using humic acid agar, Nono-

mura and Hayakawa (1988) recorded average counts of 3.6×10^4 cfu per gram dry weight soil for a number of forest soil samples collected in Japan. *Microtetraspora niveoalba* strains are particularly widely distributed albeit with counts of less than 10^3 cfu per gram dry weight of soil (Nonomura and Ohara, 1971b). In contrast, *M. malaysiensis* strains have only been isolated from two locations, namely from soil collected from below the leaf litter of mainly *Shorea* spp. in a primary lowland dipterocarp forest at Pasok, Negere Sembilan, and from a step hill dipterocarp forest at the Virgin Jungle Reserve, Gombak, Selangor in Peninsular Malaysia (Nakajima et al., 2003). *Microtetraspora fusca* and *M. glauca* have been isolated from soil samples collected in Brazil, Italy and Thailand.

Planomonospora strains have a worldwide distribution in soils of arid, temperate and tropical regions. Thiemann (1970) isolated 37 strains of *P. parontospora* from 7 out of 454 soil samples (1.5%) collected from Argentina, Chile, India, Peru and Venezuela. He also isolated 7 strains of *P. venezuelensis* from 3 out of 454 soil samples (0.7%) originating from Venezuela. Similarly, Suzuki et al. (2001b) isolated 246 *Planomonospora* strains from 137 out of 1200 soil samples; 94% of these isolates were from neutral to slightly alkaline soils (pH 7.0–9.0). Strains assigned to the *P. parontospora* group were recovered from 131 of these soil samples, notably from ones collected in Ecuador, Greece and India. Strains classified in the *P. venezuelensis* group were isolated from 13 soil samples (1.1%) collected in Bolivia, Cyprus, Egypt, Greece, India, Japan, New Caledonia and Turkey. The single strains of *P. alba* and *P. sphaerica* were isolated from soil samples collected from The Sudan and India, respectively (Mertz, 1994). *Planomonospora* strains have also been isolated from soil samples collected in Africa, Europe and Central and North America (Vobis, 1989b) and from the arid northeastern region of the Republic of South Africa (Kizuka et al., 1997).

Until recently, planobisporae had rarely been isolated from soil. Several strains, including the type strains of *P. longispora* and *P. rosea*, were isolated from soil samples taken from a riverbank in Venezuela (Thiemann, 1970). A few additional strains were recovered from soil samples collected from near Windhoek, Namibia (Vobis, 1989a), and from arid regions of South Africa (Kizuka et al., 1997). Suzuki et al. (2001a) have shown that planobisporae are distributed over a much wider geographical area, as they isolated 119 strains from 51 soil samples (3.5% of the samples tested) collected in Ecuador, Egypt, French Guiana, India and Madagascar. Nearly 90% of these strains were isolated from soil samples with pH values ranging from 7.0 to

7.9, results which suggest that *Planobispora* strains prefer neutral to alkaline environments. Suzuki and his colleagues were unable to isolate planobisporae from temperate regions in Europe, North America and Oceania. Planotetrasporae, in contrast to planobisporae and planomonosporae, have only been isolated from two sources. The type strain of *Planotetraspora mira* was isolated from a soil sample collected in the village of Wolung, Sichuan, People's Republic of China (Runmao et al., 1993), and *P. silvatica* from a sample of forest soil originating from Amami Island, Kagoshima Prefecture, Japan (Tamura and Sakane, 2004).

Isolation and Cultivation

Acrocarposporae, Herbidosporae and Planotetrasporae

Information was not provided on the procedures used to isolate *A. macrocephala*, *A. pleiomorpha* or *P. mira* strains from soil (Runmao et al., 1993; Tamura et al., 2000). The type strain of *A. corrugata* (previously *Streptosporangium corrugatum*) was isolated on starch casein agar supplemented with antifungal antibiotics following inoculation with a suspension of beach sand (Williams and Sharples, 1976). Similarly, *H. cretacea* strains have been isolated by plating soil suspensions onto yeast extract-starch agar (Kudo et al., 1993) and humic acid-vitamin agar (Hayakawa and Nonomura, 1987b). Members of this species have been isolated on yeast extract agar supplemented with antifungal antibiotics and plant material which had been desiccated at 28°C for at least a week prior to being ground with a blender following the addition of sterile water; the resultant plates were incubated at 28°C for 2 weeks (Kudo et al., 1993). The type strain of *P. silvatica* (Tamura and Sakane, 2004) was isolated from a sample of forest soil on humic acid-vitamin agar (Hayakawa and Nonomura, 1987b) using the yeast extract-sodium dodecylsulfate method (Hayakawa and Nonomura, 1989).

Acrocarpospora, *Herbidospora* and *Planotetraspora* strains grow well on oatmeal agar (Shirling and Gottlieb, 1966). Similarly, acrocarposporae and herbidosporae show good growth on inorganic salts starch (Shirling and Gottlieb, 1966) and yeast extract-starch agars (Kudo et al., 1993), respectively. The type strain of *Planotetraspora mira* grows well and sporulates on calcium malate (Runmao et al., 1993) and humic acid-vitamin agars (Hayakawa and Nonomura, 1987b). The type strain of *P. silvatica* grows well on glycerol-asparagine, tyrosine, and yeast-extract-malt extract agars (Tamura and Sakane, 2004).

Microbisporae, Microtetrasporae, Nonomuraea and Streptosporangiae

Dry heat treatment of air-dried soil samples and dilution plate culture with selective synthetic media are used for the preferential isolation and enumeration of some members of the family Streptosporangiaceae. The procedures outlined below have been developed for the selective isolation of the genera *Microbispora* and *Streptosporangium* (Nonomura and Ohara, 1969a; Nonomura and Ohara, 1969b) and with modifications for the isolation of other actinomycete genera, notably *Microtetraspora* and *Nonomuraea* (Nonomura and Ohara, 1971b; Nonomura and Ohara, 1971c). There is evidence (Nonomura and Hayakawa, 1988) that pretreatment of soil suspensions with yeast extract (6%, w/v) and sodium dodecyl sulfate (0.05%, w/v) at 40°C for 20 min, followed by dilution with water, activates actinomycete spores but kills vegetative cells of other soil bacteria in the suspensions. This practice leads to an increase in the counts of actinomycetes on isolation plates.

After soil samples are dried slowly at room temperature, passed through a 2-mm sieve, ground slightly in a mortar, spread on filter paper, and heated in a hot air oven at 120°C for 1 h, the number of bacteria and streptomycetes is dramatically reduced, and the isolation frequency of *Microbispora*, *Microtetraspora* and *Streptosporangium* strains is enhanced. Heated soil is incorporated directly onto isolation media, or a suspension is used to make dilution plates. Initially, arginine-vitamin (AV) and mineral-glucose-asparagine plus soil extract (MGA-SE) agars were recommended for the selective isolation of microbisporae and streptosporangiae, but two additional formulations, chitin-V and humic-vitamin (HV) agars (Hayakawa and Nonomura, 1987a; Hayakawa and Nonomura, 1987b; Nonomura, 1989c), have been developed. These media are supplemented with antifungal antibiotic(s); sometimes penicillin and polymyxin B are also used. Inoculated plates are incubated for 4–6 weeks at 30°C (or 2–3 weeks at 50°C) and examined using a light microscope with a long-working-distance objective. The highest counts and cleanest plates are usually obtained with HV agar.

Hayakawa et al. (1991) introduced an improved procedure for the selective isolation of streptosporangiae from soil. The method is based on the ability of streptosporangial spores to withstand dry heat and treatment with benzethonium chloride (BC) and the capacity of streptosporangiae to grow in the presence of leucomycin and nalidixic acid. Initially an air-dried soil sample is ground in a mortar and heated in a hot-air oven for an hour. Half a ml of a 10^{-1} dilution in water

of the heated sample is transferred to 4.5 ml of sterile 5 mM phosphate buffer (pH 7.0) containing BC at a final concentration of 0.1% (w/v). The resultant preparation is maintained at 30°C for 30 min with occasional stirring, and a portion (1 ml) is then diluted with sterile tap water (1 : 10 or 1 : 15). Inocula of 0.1 ml or 0.2 ml of the dilution are then spread over the surface of plates of HV agar supplemented with leucomycin in ethanol (1 mg per liter) and nalidixic acid (20 mg per liter) and the plates are incubated at 30°C for 3–4 weeks. Actinomycetes which appear on the plates are examined by light microscopy (600X) and assigned to genera on the basis of characteristic morphological properties.

Microbispora strains can be preferentially isolated by treating suspensions of dry heat pretreated soil samples with 1.5% phenol at 30°C for 30 min, diluting in water, and plating onto HV agar supplemented with nalidixic acid (20 mg per liter). *Microbispora karnatakensis* (Rao et al., 1987) was isolated by plating a suspension of soil onto inorganic salts-starch agar (Küster, 1959).

Microtetraspora fusca, *M. glauca* and *M. malaysiensis* were isolated from soil samples using methods that have not been disclosed (Thiemann et al., 1968b; Nakajima et al., 2003). However, the pretreatment procedure described above has been used to isolate several *Nonomuraea* species, including *N. helvata*, *N. pusilla*, *N. roseoviolacea* and *N. spadix* (Nonomura and Ohara, 1971c). *Nonomuraea* spores appear to be particularly resistant to dry heat at 100–120°C thereby allowing the slow-growing nonomuraea to develop into recognizable colonies on dilution plates. Soil dilutions are plated onto various media, including AV and MGA-SE agars, and incubated for several weeks at 28–30°C (Nonomura and Ohara, 1971b). *Microtetraspora niveoalba* was isolated from dry-heated soil on MGA-SE agar incubated at 40°C for 1 month. Similarly, *M. glauca* strains have been isolated on plates of this medium incubated at 30°C.

Other *Nonomuraea* (previously *Microtetraspora*) species, such as *N. roseola* and *N. salmonea*, have been isolated from soil by Soviet investigators who supplemented media with antibiotics to improve their selectivity. Lavrova et al. (1972) added rubomycin (5, 10 or 20 µgml⁻¹) to medium no. 2 of Gauze et al. (1957); Preobrazhenskaya et al. (1975) added bruneomycin (0.5, 1 or 2 µgml⁻¹) or streptomycin (0.5, 1 or 2 µgml⁻¹). The use of these antibiotics led to the growth of more *Nonomuraea* colonies on isolation plates while reducing the number of streptomycetes. In contrast, *N. ferruginea* and *N. spiralis* were isolated by plating soil suspensions onto oatmeal agar or Gauze's no. 1 medium without addition of selective antibiotics (Meyer, 1979).

Microbisporae, microtetrasporae, nonomuraea and streptosporangiae grow well on rich media, including Bennett's (Jones, 1949), glucose-yeast extract (Waksman, 1950), oatmeal (ISP medium 3; Difco 0771), and yeast extract-malt extract agars (ISP medium 2 [Difco 0770]; Shirling and Gottlieb, 1966). Oatmeal-yeast extract agar is recommended for the growth of mesophilic microbisporae and glycerol agar for the corresponding thermophilic strains (Nonomura, 1989a). Streptosporangiae grow well and produce an abundant aerial spore mass on oatmeal-yeast extract agar (Nonomura and Ohara, 1960). Good growth of vegetative and sporing aerial mycelia was obtained for *Microtetraspora fusca* and *M. glauca* on Hickey and Tresner (1952) agar. *Microtetraspora malaysiensis* strains grow well on yeast-malt extract agar (Nakajima et al., 2003). *Microtetraspora niveoalba* requires B vitamins for growth on synthetic media (Nonomura and Ohara, 1971b).

Planobisporae and Planomonosporae

BAITING WITH NATURAL SUBSTRATES. The procedures used to isolate *Planobispora* and *Planomonospora* strains from soil were not revealed by Thiemann and his colleagues (Thiemann et al., 1967; Thiemann and Beretta, 1968a). However, members of these taxa have been isolated from soil by baiting with natural substrates (Couch, 1954; Bland and Couch, 1981) as follows: a small amount of soil, approximately one level teaspoonful, is placed in a sterile Petri dish and flooded with sterile water (distilled water or filtered soil or charcoal water extracts may be used). Added pollen and hair float at the water surface; various types of pollen have been employed including that from members of the genera *Liquidamber*, *Pinus* and *Sparganium* (Schäfer, 1973). After 1–4 weeks, examination of the water surface with a dissecting microscope (100X) and strong horizontal lighting should reveal white glistening spore vesicles formed in the air at the surface of the water by spore vesicle-forming members of the families Micromonosporaceae and Streptosporangiaceae. The characteristic two-spored vesicles of *Planobispora* develop on long aerial hyphae growing between the baits. Similarly, sporulating aerial hyphae of *Planomonospora* strains grow on pollen grains. Single spore vesicles or bundles of them can be picked up with a thin needle and placed on the surface of agar media in small Petri dishes. After 2–4 weeks, the young colonies can be transferred to slant cultures. Similarly, *Planomonospora alba* strain A82600^T and *Planomonospora sphaerica* strain A15460^T were isolated by immersing a soil sample in water enriched for growth of microorganisms with motile spores,

with sterile grass floating on the water surface as bait (Mertz, 1994).

USE OF FLOODING SOLUTIONS, CENTRIFUGATION AND HUMIC ACID GELLAN GUM. A multistage procedure was developed by Suzuki et al. (2001a) for the selective isolation of planobisporae from soil. Air-dried soil samples (500 mg) are heated at 90°C for 60 min in a hot-air oven and then cooled to room temperature. Each heat treated sample is added to 2 ml of flooding solution (0.1% skim milk [neutralized], 0.01% Tween, 100 µgml⁻¹ nalidixic acid in 5 mM *N*-cyclohexyl-2-aminoethanesulfonic acid [CHES]; pH 9.0) and incubated at 35°C for 60 min with occasional stirring to stimulate zoospore motility. After centrifugation (1000 g) for 10 min at room temperature, 800 µl of supernatant is gently transferred to a sterile tube; 100-µl aliquots of this preparation are spread over humic acid-trace salts gellan gum medium (HSG) supplemented with cycloheximide (50 µgml⁻¹), enoxacin (20 µgml⁻¹), nalidixic acid (50 µgml⁻¹), nystatin (50 µgml⁻¹), sodium ampicillin (2 µgml⁻¹), streptomycin sulfate (1 µgml⁻¹) and trimethoprim (50 µgml⁻¹). Following incubation at 32°C for 14–21 days, planobisporae colonies growing on the HSG plates are recognized by their characteristic morphological features, as seen using a 40× long working distance objective lens. Pure cultures are isolated by streaking onto HSG medium and tested for zoospore production using flooding solution containing 0.1% skim milk in 5 mM CHES (pH 9.0).

A similar multistage procedure is available for the selective isolation of planomonosporae from soil (Suzuki et al., 2001b). Air-dried soil samples (500 mg) are heated at 100°C for 60 min in a hot-air oven and cooled to room temperature. Each heat treated sample is added to 2 ml of sterile flooding solution (0.1% skim milk in 5 mM *N*-cyclohexyl-2-aminoethanesulfonic acid [CHES]; pH 9.0) and incubated at 32°C for 90 min with occasional stirring to stimulate motility. The soil suspension is centrifuged (1000 g) for 10 min at room temperature, incubated at 32°C for 60 min, and 500 µl of supernatant gently transferred to a sterile tube and 100-µl aliquots spread over HSG medium supplemented with cycloheximide (50 µgml⁻¹), enoxacin (20 µgml⁻¹), nalidixic acid (20 µgml⁻¹), nystatin (50 µgml⁻¹), sodium ampicillin (2 µgml⁻¹) and trimethoprim (20 µgml⁻¹). Inoculated plates are incubated at 35°C for 14–21 days. Colonies of actinomycetes are observed directly under a phase-contrast microscope using a 40X long distance working objective lens.

Planomonospora colonies, identified using morphological features (clavate spore vesicles containing single spores), are purified by single colony isolation on HSG plates and incubated at

35°C for 14 days. Isolates are tested for motility with flooding solution containing 0.1% skim milk in 5 mM CHES (pH 9.0). Isolates with motile spores can be assigned to two groups on the basis of morphological features: the *P. parontospora* group (spore vesicles arranged in double parallel rows resembling bananas) and the *P. venezuelensis* group (spore vesicles arranged in palm leaf patterns).

Planobisporae and planomonosporae grow on standard media used for cultivating streptomycetes (Waksman, 1961); the first signs of visible growth appear after 3–4 days at 28–30°C. *Planobispora longispora* produces aerial hyphae and abundant spore vesicles on calcium malate, soil extract, and yeast extract-malt extract agars (Shirling and Gottlieb, 1966). Vesicular development in *P. rosea* is promoted by all media on which aerial mycelium is formed, notably soil extract and Hickey-Tresner agars. Spore vesicle development in *Planomonospora* strains is especially abundant on Bennett's, Hickey-Tresner, oatmeal and soil extract agars (Thiemann et al., 1967; Vobis, 1989b).

Media for Isolation and Cultivation

The following are the recipes for those media mentioned in the preceding section that are not commercially available. Quantities are for 1 liter of distilled water unless otherwise stated.

ISOLATION MEDIA Arginine-Vitamin (AV) Agar (Nonomura and Ohara, 1969a)

L-Arginine	0.3 g
Glucose	1.0 g
Glycerol	1.0 g
K ₂ HPO ₄	0.3 g
MgSO ₄ · 7H ₂ O	0.2 g
NaCl	0.3 g
Agar	15 g

Trace Salts Solution

CuSO ₄ · 5H ₂ O	1.0 mg/ml
Fe ₂ (SO ₄) ₃	10.0 mg/ml
MnSO ₄ · 7H ₂ O	1.0 mg/ml
ZnSO ₄ · 7H ₂ O	1.0 mg/ml

Adjust to pH 8.0.

Vitamins (final weight in medium): 0.5 mg each of p-aminobenzoic acid, calcium pantothenate, inositol, niacin, pyridoxine HCl, riboflavin, thiamine HCl; 0.25 mg of biotin.

Antibiotics: cycloheximide, 50 mg; nystatin, 50 mg; nalidixic acid, none or 20 mg; penicillin G, none or 0.8 mg; polymyxin, none or 4 mg. Adjust pH to 6.4.

Chitin-V Agar (Hayakawa and Nonomura, 1984)

Colloidal chitin	2 g (dry weight)
CaCO ₃	0.02 g
FeSO ₄ · 7H ₂ O	10 mg

K ₂ HPO ₄	0.35 g
KH ₂ PO ₄	0.15 g
MgSO ₄ · 7H ₂ O	0.2 g
MnCl ₂	1 mg
NaCl	0.3 g
ZnSO ₄ · 7H ₂ O	1 mg
Agar	18 g

Add B vitamins, as for AV agar, and cycloheximide, 50 mg. Adjust pH to 7.2.

Humic Acid-Trace Salts Gellan Gum Medium (Suzuki et al., 2001a)

Nitrohumic acid	0.5 g
CaCl ₂	0.33 g
FeSO ₄ · 7H ₂ O	1 mg
MnCl ₂ · 4H ₂ O	1 mg
NiSO ₄ · 6H ₂ O	1 mg
ZnSO ₄ · 7H ₂ O	1 mg
N-cyclohexyl-2-amino-ethanesulfonic acid	1 g
Gellan gum	7 g

Obtain the nitrohumic acid from Tokyo Chemical Industry, Tokyo, Japan and the gellan gum from Wako Pure Chemicals, Osaka, Japan. Adjust pH to 9.0. Autoclave at 121°C for 20 min.

Humic Acid-Trace Salts Gellan Gum Medium (Suzuki et al., 2001b)

Nitrohumic acid	0.5 g
CaCl ₂	0.33 g
FeSO ₄ · 7H ₂ O	0.001 g
MnCl ₂ · 4H ₂ O	0.001 g
NiSO ₄ · 6H ₂ O	0.001 g
ZnSO ₄ · 7H ₂ O	0.001 g
N-cyclohexyl-2-amino-ethanesulfonic acid	1 g
Gellan gum	7 g

Obtain the nitrohumic acid from Tokyo Chemical Industry, Tokyo, Japan and the gellan gum from Wako Pure Chemicals, Osaka, Japan. Adjust pH to 9.0. Autoclave at 121°C for 20 min.

Humic-Vitamin (HV) Agar (Hayakawa and Nonomura, 1984; Nonomura, 1984)

Humic acid (see below)	1 g
CaCO ₃	0.02 g
FeSO ₄ · 7H ₂ O	0.01 g
KCl	1.7 g
MgSO ₄ · 7H ₂ O	0.05 g
Na ₂ HPO ₄	0.5 g
Agar	18 g

Humic acid (1 g) is used in the form of an alkaline solution. Artificial humic acid prepared from glycine and urea may be employed, as may natural humic acid from soil humus, but the pale brown humic acid designated as "Rp type" gives the best results. Add B vitamins, as for AV agar and cycloheximide, 50 mg; adjust to pH 7.2.

Inorganic Salts-Starch Agar (Küster, 1959)

Solution I: Difco soluble starch, 10 g. Make a paste of the starch with a small amount of cold distilled water and bring to a volume of 500 ml.

Solution II:

CaCO ₃	2 g
K ₂ HPO ₄ (anhydrous salt)	1 g
MgSO ₄ · 7H ₂ O	1 g

NaCl	1 g
(NH ₄) ₂ SO ₄	2 g
Distilled water	500 ml
Trace salts solution	1 ml

Adjust to pH 7–7.4. Mix solutions I and II and add 20 g of agar. Trace salts include FeSO₄ · 7H₂O, 0.1 g; MnCl₂ · 4H₂O, 0.1 g; ZnSO₄ · 7H₂O, 0.1 g; and distilled water, 100 ml.

Medium No. 1 (Gauze et al., 1957)

Starch	20 g
FeSO ₄ · 7H ₂ O	0.01 g
KNO ₃	1 g
K ₂ HPO ₄	0.5 g
MgSO ₄	0.5 g
NaCl	0.5 g
Agar	30 g

Adjust to pH 7.2–7.4.

Mineral Glucose Asparagine-Soil Extract (MGA-SE) Agar (Nonomura and Ohara, 1971b)

L-Asparagine	1 g
Glucose	2 g
K ₂ HPO ₄	0.5 g
Soil extract	200 ml
Distilled water	800 ml
Agar	20 g

Add antibiotics: cycloheximide, 50 mg; nystatin, 50 mg; benzylpenicillin, 0.8 mg; and polymyxin B, 4 mg. To prepare the soil extract, add 1000 g of soil to 1 liter water, autoclave for 30 min, then decant and filter. Adjust to a final pH of 8.0.

CULTIVATION MEDIA

Bennett's Agar (Jones, 1949)

Beef extract	1 g
Glucose	10 g
N-Z amine A (enzymatic digest of casein)	2 g
Yeast extract	1 g
Agar	15 g

Adjust to pH 7.3 with NaOH.

Modified Bennett's agar can be used, where glucose is replaced by glycerol (10 g) and N-Z amine A by Bacto-casitone (2 g; Difco).

Calcium Malate Agar (Waksman, 1961)

Calcium malate	10 g
K ₂ HPO ₄	0.5 g
NH ₄ Cl	0.5 g
Agar	15 g

Czapek Agar (Waksman, 1950)

Sucrose	30 g
FeSO ₄ · 7H ₂ O	0.01 g
KCl	0.5 g
K ₂ HPO ₄	1 g
MgSO ₄ · 7H ₂ O	0.5 g
NaNO ₃	3 g
Agar	15 g

After components are dissolved, dispense the medium into flasks or tubes and then autoclave. For peptone-Czapek agar, substitute 5 g of peptone for 3 g of NaNO₃ (Bland and Couch, 1981).

Glucose-Yeast Extract Agar (Waksman, 1950)

Glucose	10 g
Yeast extract (50% solution)	20 ml
Agar	15 g

Adjust to pH 6.8.

Glycerol Agar (Nonomura and Ohara, 1969b)

Casamino acids	2 g
Glycerol	5 g
K ₂ HPO ₄	0.3 g
MgSO ₄ · 7H ₂ O	0.5 g
NaCl	0.3 g
Agar	20 g

Add trace salts and B vitamins as for AV agar; adjust final pH to 7.2.

Hickey-Tresner Agar (Hickey and Tresner, 1952)

Amidax or dextrin	10 g
Beef extract	1 g
N-Z amine A or tryptone	2 g
Yeast extract	1 g
CoCl ₂ · 6H ₂ O	2 mg
Agar	20 g

Obtain Amidax from Corn Products Refining, Argo, Illinois, and beef extract, tryptone, and yeast extract from Difco. Adjust to pH 7.3.

Medium No. 2 (Gauze et al., 1957)

Glucose	10 g
Peptone	5 g
NaCl	10 g
Hottinger's broth	30 ml
Agar	15 g

Adjust to pH 7.0.

Oatmeal Agar (Bland and Couch, 1981)

Baby oatmeal	65 g
Agar	15 g

Autoclave for 30 min, leave for 24 h, then autoclave again before dispensing.

Soil Extract Agar (Thiemann et al., 1968b)

Air-dried garden soil	30 g
Agar	20 g
Tap water	1 liter

Adjust pH to 7.0. Autoclave for 20 min at 120°C.

Yeast Extract-Malt Extract Agar (Pridham et al., 1956–57)

Bacto-dextrose (Difco)	4 g
Bacto-malt extract (Difco)	10 g
Bacto-yeast extract (Difco)	4 g

Adjust to pH 7.3, then add 20 g of Bacto-agar. Liquify agar by steaming at 100°C for 15–20 min.

Preservation of Cultures

The most convenient method for short-term storage is by serial transfer from agar slants of appropriate media (see above) every two months (Meyer, 1989). The tubes should be tightly closed

with cotton plugs dipped in melted paraffin wax. Sporulated spore cultures can be stored at 5°C and at room temperature. Lyophilization, storage in liquid nitrogen, and freezing in glycerol can be used for long-term preservation (Wellington and Williams, 1978; Meyer, 1989).

For lyophilization, the spore suspension or vegetative mycelium is suspended in a suitable fluid, such as serum plus 7.5% (w/v) glucose or skimmed milk plus 7.5% (w/v) glucose. For storage in liquid nitrogen, the microorganisms are inoculated into small test tubes containing the appropriate medium and incubated until satisfactory growth is visible. The tubes are then closed with cotton plugs dipped in melted paraffin wax and placed in a liquid nitrogen container. Glycerol suspensions are prepared by scraping aerial growth or substrate mycelium or both from heavily inoculated plates and making heavy suspensions in 3 ml of aqueous glycerol in small (e.g., bijoux) bottles, which are stored at -20°C. The frozen glycerol suspensions serve both as a practical means of long-term preservation and as convenient source of inoculum. Working inocula are obtained by thawing suspensions at room temperature prior to treating as for broth cultures. After use, glycerol suspensions are promptly frozen and stored again at -20°C.

Identification

Streptosporangiaceae strains can be distinguished from all other actinomycetes using a combination of chemotaxonomic and morphological features. Members of the family show a range of morphological properties but are relatively homogeneous from a chemotaxonomic perspective (Table 1). Simplified procedures are available for detecting chemical markers, notably, cell wall constituents (Staneck and Roberts, 1974; Uchida et al., 1977; Uchida et al., 1999; Hancock, 1994), fatty acids (Suzuki and Komagata, 1983; Kroppenstedt et al., 1990), menaquinones (Collins et al., 1977; Kroppenstedt, 1982; Suzuki et al., 1983; Minnikin et al., 1984) and polar lipids (Suzuki et al., 1983; Minnikin et al., 1984). Procedures such as these are being progressively complemented or replaced by molecular systematic methods, including the use of oligonucleotide primers (Monciardini et al., 2002) and 16S rRNA gene sequences (Stackebrandt et al., 1997; Tamura et al., 2000; Stach et al., 2003).

Primary diagnostic chemotaxonomic data can be gained by examination of whole-organism hydrolysates (Lechevalier and Lechevalier, 1980). Unidimensional thin layer chromatography will determine whether an organism contains diaminopimelic acid and whether the latter

is in the *LL*- or *meso*- form. Sporoactinomycetes rich in *LL*-A₂pm can be provisionally assigned to the genus *Streptomyces* (see The Family Streptomycetaceae, Part I: Taxonomy in this Volume and The Family Streptomycetaceae, Part II: Molecular Biology in this Volume). The detection of *meso*-A₂pm and madurose with the absence of characteristic sugars serves to separate strains of Streptosporangiaceae from those of *Actinoplanes* and related genera, *Nocardia* and related genera, *Pseudonocardia* and related genera, *Nocardiopsis* and related genera, and *Thermomonospora* and related genera, but not from the genera *Dermatophilus* and *Frankia*. The latter can be distinguished readily from *Streptosporangium* and allied taxa on morphological grounds. To date, the presence of madurose is associated with wall chemotype III actinomycetes, although there is an unconfirmed report of this sugar from a wall chemotype I actinomycete with a streptomycete morphology (Weyland et al., 1982). The discovery of 3-*O*-methylgalactosyl (madurosyl) units in the structure of teichoic acids of an *Nonomuraea roseoviolaceae* subsp. *carminata* strain (previously *Actinomadura carminata*; Naumova et al., 1986) is also noteworthy, as madurose is not perceived to be a cell wall constituent according to Lechevalier and Lechevalier (1981a).

Wall chemotype III actinomycetes which form spore vesicles can be identified to the genus level using morphological features (Table 1), though care must be taken to distinguish between *Spirillospora* and *Streptosporangium* strains even though only the former produces motile spores (Vobis and Kothe, 1989c). Note also that the sporogenic hyphae in the spore vesicles of spirillosporae are branched, whereas those in streptosporangiae are unbranched. Chemical analyses are required if the genera *Microbispora*, *Microtetrastora* and *Nonomuraea* are to be reliably separated from the genus *Actinomadura* (Kroppenstedt et al., 1990). *Actinomadura* contain mostly hexahydrogenated menaquinones with nine isoprene units (MK-9 [H₆]) and diphosphatidylglycerol and phosphatidylinositol as predominant polar lipids (phospholipid type I sensu Lechevalier et al., 1977) whereas *Microbispora*, *Microtetrastora* and *Nonomuraea* strains have major amounts of MK-9 [H₄] saturated at positions III and IV, with major amounts of diphosphatidylglycerol, hydroxylated phosphatidylethanolamine, uncharacterized glycolipids, and a glucosamine-containing phospholipid (type IV phospholipid pattern sensu Lechevalier et al., 1977).

The continued separation of the genera *Microbispora*, *Microtetrastora* and *Nonomuraea* solely on morphological criteria is questionable. *Microbispora* is distinguished from related genera

(Table 1) primarily by the formation of paired spores on aerial hyphae. These are either sessile or borne on short sporophores. The latter in *M. rosea* were found to attach to the base of the spore by a ball and socket arrangement (Williams, 1970). *Microbispora* species are currently separated by using a range of phenotypic properties (Table 3).

Cultures of *M. aerata*, *M. amethystogenes*, and *M. parva* deposit crystals with a metallic sheen in the medium, particularly when grown on Pabulum extract agar (Lechevalier and Lechevalier, 1957) for about 10 days (Gerber and Lechevalier, 1964). These crystals are composed of iodinin (1,6-phenazinediol-5,10-dioxide), a red, water-soluble pigment. In addition, *M. aerata* produces two brown-yellow pigments (2-aminophenoaxazine-3-one and 1,6-phenazinediol), a yellow pigment (2-acetamidophenoxazine-3-one; Gerber and Lechevalier, 1964), and an orange pigment (1,6-phenazinediol-5-oxide; Gerber and Lechevalier, 1965).

Microtetrasporae can be recognized by their ability to produce short spore chains which typically contain four spores. The identification of species within the genus is still based on phenotypic properties, notably on the color of the aerial and substrate mycelium (Table 4).

Nonomuraea strains are distinguished from members of related genera by their ability to form chains of spores or pseudovesicles on aerial hyphae (Figs. 10–12). The constituent species may be distinguished by means of spore chain morphology, spore wall ornamentation, color of mature sporulated aerial mycelium, and substrate mycelium pigmentation (Table 5). Nevertheless, identification of many of these species is difficult because in most instances only one (the type) strain or a few strains have been examined. Even when several strains have been studied, the

results of biochemical and physiological tests have proved to be variable or inconsistent when data from the literature are compared. However, numerical taxonomic evidence indicates that most of the validly described taxa merit species status (Goodfellow et al., 1979; Goodfellow and Pirouz, 1982).

Streptosporangium species can be distinguished from one another using a combination of phenotypic properties, notably morphological features (Table 6). They can be separated by spore vesicle size, sporangiophore length, spore shape, aerial spore mass color, and substrate mycelium pigmentation and subdivided according to the nature of the vesicular wall. At one extreme, the spore vesicular membrane of *S. fragile* is so thin that it cannot be detected by light microscopy (Shearer et al., 1983). This feature may lead to difficulty in differentiating

Fig. 11. *Nonomuraea spiralis*, IMET 9621^T. Sporulating aerial mycelium. Oatmeal-nitrate agar, 28°C, 18 days. From Meyer (1989), with permission.

Streptosporangium from *Nonomuraea* strains, as members of some species of the latter produce pseudovesicles covered by a slimy substance (Nonomura and Ohara, 1971c). The remaining species of *Streptosporangium* form thin vesicular membranes that are readily disrupted in water. *Streptosporangium amethystogenes* produces violet crystals of iodine after a month's incubation at 30°C on oatmeal-yeast extract agar.

Improved phenotypic tests are needed for the identification of unknown streptosporangiae. Clearly such tests should be based on a representative set of strains. Whitham (1988) generated a probability matrix on the basis of 26 diagnostic properties for the identification of unknown streptosporangiae to established and novel *Streptosporangium* species. In a continuation of these studies, Kim (1993) assigned 65 out of 70

marker *Streptosporangium* strains and 12 out of 131 putative streptosporangiae isolated from soil to known species of *Streptosporangium*. A further 19 of the soil isolates were identified to known species when less stringent cut-off points were adopted for a positive identification.

The genera *Planobispora*, *Planomonospora* and *Planotetraspora* may be distinguished by the shape of their spore vesicles and by the number of encased spores. *Planobispora* and *Planomonospora* species can be separated using a judicious selection of phenotypic properties (Table 7). *Planobispora longispora* and *Planobispora rosea* have many properties in common (Goodfellow and Pirouz, 1982) but can be separated by using cultural characteristics (Thiemann, 1974a). *Planobispora longispora* produces a hyaline- to creamish-colored substrate mycelium and a

white aerial mycelium whereas *P. rosea* has a rose-colored substrate mycelium and an aerial mycelium with a light rose tinge.

The type strain of *P. mira*, unlike that of *P. silvatica*, produces acid from lactose, mannitol, mannose and rhamnose and uses glucose, mannitol and xylose as sole carbon sources. Conversely, the *P. silvatica* strain degrades xanthine and uses melibiose and raffinose as sole carbon sources. The two strains can also be distinguished using colonial characteristics.

Planomonospora parontospora and *P. venezuelensis* strains can be distinguished by the morphological arrangement of their spore vesicles (Figs. 8 and 9), different menaquinone profiles (Collins et al., 1984), and the characteristic color of the mycelium (Thiemann, 1974a). *Planomonospora sphaerica* can be distinguished from the other members of the genus by its ability to

form large spherical bodies when grown on inorganic salts starch agar (Mertz, 1994). Members of the genera *Acrocarpospora* and *Herbidosporea* can also be recognized on morphological grounds (Table 1). The identification of species of *Acrocarpospora* is based on the discontinuous distribution of a few phenotypic properties (Table 7).

Metabolism and Genetics

Little is known about the genetics and metabolism of members of the family Streptosporangiaceae despite their potential importance in exploitable biology, notably in the discovery of novel bioactive compounds. However, vectors capable of stably maintaining large segments of actinomycete DNA in *Escherichia coli* and of

Table 8. Characteristics distinguishing the type strains of *Acrocarpospora* species.

From Whitham et al. (1993) and Tamura et al. (2000).

integrating site specifically in the *Streptomyces* genome have been developed to facilitate the manipulation of uncommon actinomycete strains, including streptosporangiaceae and related taxa (Donadio et al., 2002). These vectors, designated “ESAC,” an abbreviation for “*E. coli*-*Streptomyces* artificial chromosome,” are suitable for the reconstruction of gene clusters from small segments of the cloned DNA, the preparation of large insert libraries from unusual actinomycete strains, and the construction of environmental libraries. Other examples of heterologous expression of entire gene clusters in model actinomycetes have been reported (Piel et al., 2000; Tang et al., 2000; Kwon et al., 2001).

The gene cluster coding for the biosynthesis of glycopeptide antibiotic A40926 in *Nonomuraea* strain ATCC 39727 has been isolated and characterized by Sosio et al. (2003). This glycopeptide, a member of the teichoplanin family of glycopeptides, is the precursor of dalbavancin, a second generation glycopeptide. Sosio and her colleagues also isolated the novel compound, dechloromannosyl-A40926 aglycone, following the construction of a *Nonomuraea* mutation by deleting *dbr* open reading frames 8–10. Prauser (1984) reported that attempts to isolate phage from Streptosporangiaceae strains had been unsuccessful.

Applications

Members of the family Streptosporangiaceae are expected to be an increasingly rich source of commercial products, notably antibiotics and enzymes. “*Microtetraspora tyrrkensis*” produces fluvirucins active against influenza A virus (Tomita et al., 1991); *Microbispora rosea*, deoxycephalomycin B (Okazaki and Naito, 1985); *Microbispora* strain SCC 1438, a novel fungal antibiotic (Patel et al., 1988); *N. roseoviolacea*,

carminomicins (Nakagawa et al., 1983; Nakagawa et al., 1989); *N. rubra*, maduromycin (Fleck et al., 1978), *N. pusilla*, actinotiocin (Tamura et al., 1973), and *N. spiralis*, pyralomicin (Naganawa et al., 2002). Similarly, *Streptosporangium albidum* produces aculeximycin (Murata et al., 1989); *S. pseudovulgare*, sporamycin (Komiya et al., 1977); *S. roseum*, maytansin-type ansamacrolactam (Hacene et al., 1998), sporangiosamycin (Gazhal and Abl El-Aziz, 1993), and thiosporamycin (Celmer et al., 1978); *S. violaceochromogenes*, platomycins A and B (Takasawa et al., 1975) and victomycin (Kawamoto et al., 1975), and *S. vulgare*, sporacuaracins A and B (Atsushi et al., 1978). A novel anthracycline antibiotic has been isolated from *S. fragile* (Shearer et al., 1983), an antitumor antibiotic from an organism resembling *S. pseudovulgare* (Umezawa et al., 1976) and unspecified antimicrobial agents from *Microbispora indica* and *M. karnatakensis* (Rao et al., 1987).

Microbispora rosea is an excellent source of D-xylose (glucose) isomerase (Crueger and Crueger, 1982), which converts D-glucose into D-fructose. The enzyme is used to produce D-fructose on a commercial scale, and its biosynthesis, purification, and immobilization, as well as its application for the production of high fructose syrup, have been the subject of many reports and patents (Crueger and Crueger, 1984). Similarly, cystathionine γ -lyase has been detected in strains of *Streptosporangium* (Nagasawa et al., 1984). This enzyme has been shown to catalyze the α , γ -elimination reaction of L-cystathionine and also the γ -replacement of L-homoserine in the presence of various thiol compounds (Kanzaki et al., 1986a). An efficient method based on the reaction of γ -replacement has been developed (Kanzaki et al., 1986b) for the preparation of L-cystathionine, a product that may be useful because a deficiency of this compound has been observed in the brains of homocystinuric

patients (Gerritsen and Waisman, 1964). The procedure allowed the total conversion of *O*-succinyl-L-homoserine and L-cysteine into L-cystathionine. *Microbispora rosea* also produces exoxylanases (Kusakabe et al., 1969).

Thermophilic microbisporae synthesize a wide range of enzymes that are involved in the degradation and modification of heteropolysaccharides, notably celluloses, lignocelluloses, and hemicelluloses (Henssen and Schnepf, 1967; McCarthy, 1987; Crawford, 1988). These enzyme systems have the potential for novel application in biotechnological processes, particularly for the enzymatic generation of fermentable sugar from agricultural residues (McCarthy et al., 1988; Zimmermann, 1989).

The Family Nocardioaceae

REINER MICHAEL KROPPESTEDT AND LYUDMILA I. EVTUSHENKO

Phylogeny and Taxonomy

The family Nocardioaceae was created by Rainey and co-workers in 1996 (Rainey et al., 1996). One year later, this family was combined with Streptosporangiaceae and Thermomonosporaceae into Streptosporangiaceae, which is one of the ten suborders of the order Actinomycetales (Stackebrandt et al., 1997). Originally the family Nocardioaceae harbored only the type genus *Nocardio*. Later, Zhang included *Thermobifida* into this family, a new genus which was the home for the two misclassified *Thermomonospora* species *Tm. alba* and *Tm. fusca* (Zhang et al., 1998). Recently, a third genus *Streptomonospora* was added to this family (Cui et al., 2001). The original spelling *Streptimonospora* has been corrected to *Streptomonospora* in the notification list of the same issue of the IJSEM.

Nocardio

At present, the genus *Nocardio* harbors 14 species and one subspecies:

- Nocardio alba* Grund and Kroppestedt, 1990
- Nocardio dassonvillei* subsp. *albirubida* (Grund and Kroppestedt, 1990) Evtushenko et al., 2000
- Nocardio dassonvillei* subsp. *dassonvillei* (Brocq-Rousseau, 1904), Meyer, 1976
- Nocardio compostus* Kämpfer et al., 2002
- Nocardio exhalans* Peltola et al., 2001
- Nocardio halophila* Al-Tai and Ruan, 1994
- Nocardio halotolerans* Al-Zarban et al., 2002
- Nocardio kunsanensis* Chun et al., 2000
- Nocardio listeri* Grund and Kroppestedt, 1990
- Nocardio lucentensis* Yassin et al., 1993
- Nocardio prasina* (Grund and Kroppestedt, 1990) Yassin et al., 1997
- Nocardio synnemataformans* Yassin et al., 1997
- Nocardio trehalosi* (ex Dolak et al., 1980) Evtushenko et al., 2000
- Nocardio tropica* Evtushenko et al., 2000
- Nocardio umdischolae* Peltola et al., 2001.

The taxonomic positions and designations of some species and subspecies currently belonging to the genus *Nocardio* or referred previously to this genus were changed from time to time (Table 1), reflecting the steps in the development of actinomycete classification. Originally, morphology and physiology were the only criteria used to differentiate *Nocardio* from other mesophilic aerobic actinomycete genera such as *Streptomyces* and *Nocardia*, which also produce conidia- or arthrospores on aerial mycelia. Although morphology is a very valuable character for identification of aerobic spore forming actinomycetes, it has limited value in classification. The same morphological structures are found in different actinomycete genera and a high degree of overlap exists in morphology between phylogenetically unrelated taxa (Gordon and Horan, 1968; Goodfellow and Cross, 1984; Stackebrandt et al., 1983; Stackebrandt, 1986).

Table 2 lists the most important morphological characters of the major genera of sporoactinomycetes.

With the introduction of chemical markers, the taxonomy of Actinomycetales was on a solid basis. The first chemotaxonomic properties used in classification of actinomycetes were amino acids and sugars determined in purified cell walls (Cummins and Harris, 1956; 1958; Romano and Sohler, 1956; Hoare and Work, 1957; Cummins, 1962). This work was continued by Lechevalier and Lechevalier (Lechevalier and Lechevalier, 1970a; Lechevalier and Lechevalier, 1970b), who analyzed the cell walls and whole cells of more than 600 strains of actinomycetes. The results of this study led to the concept of “cell wall chemo types.” The authors used specific differences in the major constituents of cell wall (amino acid composition and presence of arabinose and galactose) to differentiate aerobic spore-forming actinomycetes into four groups: I (LL-2,6-diaminopimelic acid-[A₂pm] and glycine as diagnostic components), II (glycine and meso-2,6-diaminopimelic acid combined sometimes with 2,6-diamino-3-hydroxypimelic acid), III (meso-A₂pm only), and IV (meso-A₂pm com-

bined with arabinose and galactose; Lechevalier and Lechevalier, 1970a).

On the basis of the chemical data and some specific morphological characters, Lechevalier and Lechevalier (Lechevalier and Lechevalier, 1970a; Lechevalier and Lechevalier, 1970b) created the new actinomycete genus *Actinomadura*. This genus harbored three species, *A. madurae*, *A. pelletieri*, and *A. dassonvillei*. The two unifying characters of these three aerobic actinomycete species were: 1) the ability to produce spore chains on aerial mycelia and 2) cell wall chemotype III, which corresponds to the peptidoglycan type A1γ (Schleifer and Kandler, 1972), i.e., *N*-acetyl-muramic acid, *N*-acetyl-glucosamine, alanine, glutamic acid, and *meso*-2, 6-diaminopimelic acid. Using cell wall chemistry, it

was possible to separate these three *Actinomadura* species from morphologically related taxa showing a different cell wall composition, e.g. type I *Streptomyces*, IV *Nocardia*, *Pseudonocardia* and related genera. However, using only morphology and this limited set of chemical markers, the genus *Actinomadura* quickly became a dumping ground for many unrelated chemotype III isolates.

Progress in the classification of this taxon was achieved by the introduction of an additional chemotaxonomic marker, the sugar pattern of whole cell hydrolysates (Lechevalier and Lechevalier, 1970a; 1970b; Lechevalier et al., 1971). This made it possible to separate cell chemotype III organisms into those having the diagnostic sugar madurose (3-*O*-methyl-D-galactose), i.e.,

Table 2. Morphological differences between members of Nocardiopsaceae and some other sporoactinomycete genera.

Genus	Spore chains on special aerial hyphae	AM disintegrates into spores	Multiple cell division	Spore chains of 50 spores or more	Fragmentation of substrate mycelium	Sporangia or pseudosporangia	Motile spores

Symbols: +, present; –, absent; +/-, character is inconsistent among the species of this genus.

Abbreviations: AM, aerial mycelium.

^aIn *Glycomyces tenuis*, the aerial hyphae are not observed and the spore chains are formed on substrate mycelium.

^bSporangium-like structures or sclerotia may present in *Pseudonocardia* (the former *Amycolata*) and in *Streptomyces* (the former “*Actinosporangium*,” “*Chainia*,” etc.; see Williams et al., 1989).

^cIn streptomycetes, the spore chains may contain more than 50 spores.

Adapted from Meyer (1976); Williams and Wellington (1981); Preobrazhenskaya et al. (1982); Labeda et al. (1984; 1985); Lechevalier et al. (1986); Shearer et al. (1986); Goodfellow (1989); Kothe et al. (1989); Williams et al. (1989); Kroppenstedt et al. (1990); Zhang et al. (1997, 1998); and Chung et al. (1999).

Actinomadura, and those lacking this sugar, i.e., *Nocardioopsis*. On the basis of the characteristic development of spores, including the specific zig-zag formation of aerial hyphae before spore dispersal (Williams et al., 1974) and the lack of madurose (Lechevalier and Lechevalier, 1970b), Meyer (1976) created a new genus for *A. dassonvillei*. The name *Nocardioopsis* was selected because of the nocardia-like appearance of *N. dassonvillei*. Like *Nocardia*, *N. dassonvillei* does not produce special spore-forming hyphae but the whole aerial mycelium disintegrates completely into smooth long spores (Williams et al., 1974). Results of fatty acid and menaquinone composition analyses, as well as molecular genetic data, confirmed the separation of *Nocardioopsis* and *Actinomadura* into two genera (Agre et al., 1975; Kroppenstedt and Kutzner, 1976, 1978; Fischer et al., 1983; Athalye et al., 1984; Alderson et al., 1985). Preobrazhenskaya et al. (1982) transferred four additional *Actinomadura* species into the genus *Nocardioopsis*, i.e., *A. africana*, *A. coeruleofusca*, *A. flava* and *A. longispora*. However, subsequent chemotaxonomic studies and partial oligonucleotide sequencing of 16S ribosomal RNA from *Nocardioopsis* and *Actinomadura* revealed that these species did not belong to *Nocardioopsis* or *Actinomadura* and that both genera are heterogeneous (Poschner et al., 1985; Goodfellow et al., 1988; Streshinskaya et al., 1989; Grund and Kroppenstedt, 1990; Tapytkova et al., 1990). The heterogeneity of these taxa was underlined by the results of numerical phenetic studies (Goodfellow and Alderson, 1979; Alderson et al., 1984; Athalye et al., 1984).

In the meantime, Labeda et al. (1984) described a nocardioform actinomycete isolated from a soil sample collected in Australia. Because of its unique combination of chemical markers, the authors created a new genus, *Saccharothrix*. Although its isolate resembles *Nocardioopsis dassonvillei* morphologically and in some chemotaxonomic characters, i.e., cell wall chemotype III/C, Labeda et al. (1984) did not classify this isolate as *Nocardioopsis*: it lacked phosphatidylcholine, always present in *Nocardioopsis*, and it synthesized the menaquinones MK9-(H₄) and MK-10(H₄). In addition, Labeda (1992) detected rhamnose in whole cell hydrolysates of all *Saccharothrix* strains. This sugar has diagnostic value because it was also present in *Streptoalloteichus* (Goodfellow, 1989), *Kutzneria* (Stackebrandt et al., 1994b), *Actinokineospora* (Tamura et al., 1995), and other genera (Labeda et al., 2001). These genera have now been classified into the Actinosynnemataceae, a new family of the suborder Pseudonocardineae (Labeda and Kroppenstedt, 2000). *Saccharothrix* and related taxa can clearly be separated from *Nocardioopsis*

because rhamnose has never been detected in species of the latter genus (Fischer et al., 1983; Grund and Kroppenstedt, 1989; Grund and Kroppenstedt, 1990; Naumova et al., 2001).

Results of 16S rRNA gene sequencing revealed that *Nocardioopsis* phylogenetically occupies a separate position, apart from all other actinomycetes (Goodfellow et al., 1988; Kroppenstedt et al., 1990). Thus, the genus *Nocardioopsis* was the only genus of the family Nocardioaceae (Rainey et al., 1996), a member of the suborder Streptosporangineae (Stackebrandt et al., 1997). The results of chemotaxonomic studies on nearly all type strains of *Nocardioopsis* and related genera showed that six of the eight *Nocardioopsis* species were misclassified (Grund and Kroppenstedt, 1989; Grund and Kroppenstedt, 1990). Five of them, *N. coeruleofusca*, *N. flava*, *N. longispora*, *N. mutabilis* and *N. syringae*, were reclassified in the genus *Saccharothrix*, and one, *N. africana*, was affiliated to the genus *Microtetraspora* (Poschner et al., 1985; Goodfellow et al., 1988; Kroppenstedt et al., 1990; Table 1). Later, *Saccharothrix flava* was transferred to the new genus *Lechevalieria* (Labeda et al., 2001), and *Microtetraspora africana* together with most other species of the genus *Microtetraspora* to *Nonomuraea* (Zhang et al., 1998).

Phenetic data indicated that the remaining single member species, *N. antarctica*, was a synonym of *N. dassonvillei* (Meyer, 1989). These data were confirmed by 16S rRNA gene sequences and DNA/DNA hybridization results by Yassin et al. (1997), who transferred *N. antarctica* to *N. dassonvillei* as a later subjective synonym. DNA-DNA hybridization data and numerical analyses using fatty acid results and phenetic data showed that all tested strains of *N. dassonvillei* should be divided into two species (Fischer et al., 1983; Grund, 1987). On the basis of these results and those of some additional studies, a new species, *N. alba*, was created (Grund and Kroppenstedt, 1990). This study showed in addition that *N. dassonvillei* subsp. *prasina* was actually more closely related to *N. alba* than to *N. dassonvillei*. This subspecies was therefore transferred to *N. alba* with the revision of its name to *N. alba* subsp. *prasina*. During a study on the new *Nocardioopsis* species *N. synnemataformans*, Yassin and co-workers described on the basis of 16S rRNA gene sequences and DNA/DNA similarity studies *N. alba* subsp. *prasina* as *Nocardioopsis prasina* (Yassin et al., 1997).

A study of the cell walls of about 450 International Streptomyces Project (ISP) streptomycetes (Shirling and Gottlieb, 1972) by Pridham and Lyons (1961) revealed that some of these species did not belong to the genus *Streptomyces* because they synthesized meso- A₂pm

instead of LL-A₂pm as expected for members of the genus *Streptomyces*. The so-called “meso-DAP” streptomycetes were further characterized by Grund (1987). Two members of this group, “*Streptomyces alborubidus*” and “*Streptomyces listeri*,” were reclassified into the genus *Nocardiopsis* as *N. alborubida* and *N. listeri* (Grund and Kroppenstedt, 1990). Later, Yassin and co-workers found high similarities between the 16S rRNA gene sequences of *N. alborubida* (DSM 40465^T) and *N. dassonvillei* (Yassin et al., 1997). As DNA/DNA similarity studies revealed 77 % similarity, *N. alborubida* was transferred to *N. dassonvillei* as a later subjective synonym of this species.

Strain *N. alborubida* VKM Ac-1882^T (= DSM 40465^T) and *Nocardiopsis dassonvillei* differed on the basis of physiological test results, in macroscopic appearance (Evtushenko et al., 2000), and in chemical composition (the cell wall teichoic acid representing up to 20% of the cell wall in these species; Shashkov et al., 1997; Tul'skaya et al., 1993). On the basis of a DNA/DNA similarity of 71% obtained between VKM Ac-1882^T and other members of *N. dassonvillei*, strain VKM Ac-1882 was reclassified as *Nocardiopsis dassonvillei* subsp. *albirubida* (Evtushenko et al., 2000).

Current progress in the development of intrageneric classification of the genus *Nocardiopsis* is linked to studies of cell wall teichoic acids and the finding that these polymers and their structural elements are chemotaxonomic markers for the *Nocardiopsis* species and subspecies (Shashkov, et al., 1997; Streshinskaya et al., 1996, 1998; Tul'skaya et al., 1993, 2000).

The cell wall teichoic acids are covalently linked by phosphodiester bridges to muramic acid residues in peptidoglycan (in contrast to lipoteichoic acids, which are associated with the plasma membrane) and placed between other cell wall layers and at the cell surface (Baddiley, 1972, 2001; Archibald, 1974). The polymers are widespread among Gram-positive bacteria and may compose up to 60% (v/v) of cell envelope in some actinomycetes (Shashkov and Naumova, 1997). The following structural types of cell wall teichoic acids are (Naumova et al., 2001): 1) polymers with chains of only polyol phosphate residues or 2) polymers with chains of only glycosylpolyol phosphate residues joined by phosphodiester bonds, and 3) mixed structures of glycosyl-1-phosphate in addition to polyol phosphate residues or 4) mixed structures of alternating poly(polyol phosphate) and poly(glycosylpolyol phosphate) units. Different polyol and sugar (amino sugar) residues in the main chain and in lateral branches (which are linked to the polyol residues via glycosyl bonds, various O-acyl residues, different kinds of phos-

phodiester bonds, and some other factors) contribute additionally to the structural diversity of cell wall teichoic acids (Naumova et al., 2001). The great structural diversity of cell wall teichoic acids expressed by the information coded in various genes, their involvement in vital cell functions, and their wide occurrence in Gram-positives, suppose a certain correlation of these polymers with other taxonomic properties and their taxonomic applicability to systematics. The fact that the species within a genus have structurally dissimilar teichoic acids was reported for the first time for staphylococci (Davison and Baddiley, 1963) and later published for some other bacteria, mainly actinomycetes.

Naumova et al. (2001) summarized the data on teichoic acids of 27 strains of the genus *Nocardiopsis* and demonstrated that the structures of these polymers or their combinations are indicative of each of the seven *Nocardiopsis* species and two subspecies which were analyzed. *Nocardiopsis dassonvillei* subsp. *dassonvillei* and *N. dassonvillei* subsp. *albirubida* are characterized by polymers whose cores are composed of alternating units of both glycerol phosphate and β -N-acetyl-galactosamine glycerol phosphate residues (Fig. 1). However, the phosphodiester bond in the teichoic acid of *N. dassonvillei* subsp. *dassonvillei* is positioned at the C-3 of the amino sugar (Fig. 1a), while the polymer of VKM Ac-1882 has the phosphodiester bond located at C-4, and the C-3 position is occupied by an O-succinyl substituent in most glycosyl residues (Fig. 1b). *Nocardiopsis trehalosi* contains 1,3-poly(glycerol phosphate) substituted with β -glucosyl residues (Fig. 1c). Teichoic acid of *N. tropica* is represented by an assortment of heterogeneous 1,5-poly(ribitol phosphate) chains with lateral glycerol phosphate oligomers (Fig. 1d). The species *N. alba*, *N. listeri*, *N. lucentensis* and *N. prasina* contain different combinations of the following three polymers: unsubstituted 3,5-poly(ribitol phosphates), i.e., teichoic acid type 1 (TA1); (Fig. 1e), 1,3-poly(glycerol phosphates) substituted with N-acetylglucosamine at C-2 of glycerol residues (TA2; Fig. 1f), and 1,5-poly(ribitol phosphates) with each ribitol phosphate unit carrying a 2,4-pyruvate ketal group (TA3; Fig. 1g). In the cell walls of the strains of *N. alba*, all these three teichoic acids are present in varying amounts, *N. prasina* and *N. listeri* contain two polymers each, TA1 and TA2 (*N. prasina*), TA2 and TA3 (*N. listeri*), while *N. lucentensis* has only TA2. As each of the species and subspecies discussed is definable by the composition of teichoic acids, the polymers can be considered a valuable chemotaxonomic marker for the intrageneric taxa of *Nocardiopsis*.

Fig. 1. Fragments of the primary structure of teichoic acids typical of the *Nocardiopsis* species and subspecies (Data from Naumova et al., 2001; Shashkov et al., 1997; Streshinskaya et al., 1989, 1996, 1998; Tul'skaya et al., 1993, 2000.)

a) Poly(glycerol phosphate- β -N-acetylgalactosaminylglycerol phosphate) (*N. dassonvillei* subsp. *dassonvillei*)

b) Poly(glycerol phosphate- β -N-acetylgalactosaminylglycerol phosphate) with O-succinyl residues (*N. dassonvillei* subsp. *albirubiba*)

c) 1,3-Poly(glycerol phosphate) with with β -glucosyl residues (*N. trehalosi*)

d) 1,5-Poly(ribitol phosphate) with side chains of glycerol phosphate oligomers (*N. tropica*)

e) Unsubstituted 3,5-poly(ribitol phosphate), TA1 (*N. alba*, *N. prasina*)

f) 1,3-Poly(glycerol phosphate) with α -N-acetylglucosamine, TA2 (*N. alba*, *N. listeri*, *N. lucentensis*, *N. prasina*)

g) 1,5-Poly(ribitol phosphate) with 2,4-pyruvate ketal group, TA3 (*N. alba*, *N. listeri*)

Besides the fully identified structures of the polymers, the main products of acid degradation of the common fraction of the teichoic acids (e.g., glycerol, ribitol, glucose, glucosamine, galactosamine, pyruvate, and succinate in various combinations) can also serve as chemotaxonomic markers for the species and subspecies. Determination of some diagnostic products of alkaline hydrolysates of whole fractions of the polymers (e.g., glycerol, ribitol, their mono-, di- or triphosphates, and also certain phosphodiester) gives additional information and increases taxonomic resolution of this approach. For instance, *N. alba* and *N. listeri*, which are characterized by similar profiles of acid degradation products, can be differentiated by the presence (absence) of mono- and diphosphates of ribitol in the alkaline hydrolysates of polymers. Certain components of teichoic acids determined in acid hydrolysates of the whole cell wall without the extraction of pure polymers are also of diagnostic value (see the section "Identification" for details in this Chapter). Finally, the ^{13}C -nuclear magnetic resonance (NMR) spectra of the polymers found in the *Nocardiopsis* species and subspecies are also highly indicative, and therefore the respective intrageneric taxa are well recognizable from NMR analysis of their polymers.

The genus *Nocardiopsis* may serve as a notable example for the usefulness of cell wall teichoic acids in the differentiation and circumscription of actinomycete species. Further comparative studies of teichoic acids and related polymers in other bacterial groups and the development of simple and efficient methods for the identification of the polymers, accompanied by revision and approval of bacterial species by extensive genomic and phenetic investigations, will contribute to further progress in bacterial taxonomy and the construction of a practicable and predictive classification scheme.

Thermobifida

The history of *Thermobifida* species is complex. The name "*Thermobifida fusca*" changed from *Micromonospora* to *Thermomonospora*, then to *Actinobifida*, then back to *Thermomonospora* and recently to *Thermobifida*. The earliest observation of organisms exhibiting a clustered spore morphology typical of the genus *Thermobifida* (*Micromonospora*) was reported by Waksman et al. (1939), who applied the species epithet "fusca" to their strains. The authors considered these isolates to be the species *Micromonospora fusca*. Later, similar strains were also described by Erikson (1953), who noticed that the strains showed a tendency to produce spore clusters on substrate mycelia. On the basis of a study of

isolates from composted horse manure, Henssen (1957) created the new genus *Thermomonospora* for thermophilic actinomycetes forming single spores on aerial mycelia. Two species, *Tm. fusca* and "*Tm. lineata*," were characterized by spore clusters similar to those described by Waksman et al. (1939). However, the respective strains isolated by these authors were lost, and the species name *Tm. fusca* appeared as nomen dubium in the eighth edition of *Bergey's Manual* (Buchanan and Gibson, 1974).

The first viable strain of the genus *Thermobifida*, *Tb. alba* DSM 43795^T (the type strain of the type species; Table 1) was isolated and described by Locci et al. (1967). The authors included their isolate with the genus "*Actinobifida*," which was created previously by Krasilnikov and Agre (1964). Later, Cross and Lacey (1970) showed the high similarity in morphological characters and physiology among species of "*Actinobifida*," *Thermomonospora* and *Thermoactinomyces* and questioned the nomenclatural validity of the genus "*Actinobifida*." On the basis of the heat resistance of their endospores, the "*Actinobifida*" species were transferred (i.e., "*Ab. alba*" to *Thermomonospora* and "*Ab. dichotomica*" to *Thermoactinomyces*; Cross and Goodfellow, 1973; Skerman et al., 1980).

Subsequently, Crawford (1975) identified Forbes strain 190Th (Forbes, 1969) as *Thermomonospora fusca* sensu Henssen and proposed it as the neotype strain of *Thermomonospora fusca* (Sneath, 1992). This proposal did not result in the validation of this name because it was not included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980). On the basis of intensive study of thermophilic monosporic actinomycetes, McCarthy and Cross (McCarthy and Cross, 1984a; McCarthy and Cross, 1984b) emended the description of this species with the type strain 190Th and validated the species name *Tm. fusca* (McCarthy and Cross, 1984c).

Chemotaxonomic studies of the polar lipids, the menaquinones and the fatty acids of *Tm. alba*, *Tm. fusca* and *Tm. mesouiformis* show that these species synthesized a unique combination of chemical markers which were different from those of *Tm. curvata* (the type species of the genus *Thermomonospora*) and *Tm. chromogena* (Kroppenstedt and Goodfellow, 1992). All three species produce single spores borne mainly on aerial mycelia and sometimes on substrate mycelia, which is also in contrast to *Tm. curvata*. In addition, the spores of the *Thermobifida* species are formed in clusters, each singly on the tip of a short sporophore, with spore clusters originating from primary laterally branched aerial hyphae. Cross and Goodfellow (1973) described this structure as a repeatedly branched sporo-

phore producing dense spore heads. These clusters have never been observed in other species of the genus *Thermomonospora* (Greiner-Mai et al., 1987). It was therefore proposed to exclude these species from the genus *Thermomonospora* (Kroppenstedt and Goodfellow, 1992). Zhang confirmed this proposal when he compared the 16S rRNA gene sequences of the *Thermomonospora* type strains with all other actinomycetes (Zhang et al., 1998). Because the sequences of *Tm. alba*, *Tm. fusca* and *Tm. mesouviformis* were not related to those of any known actinomycete taxa, a new genus *Thermobifida* was established to accommodate *Tb. alba* and *Tb. fusca*. The authors also showed that the sequences of *Thermomonospora alba* and *Tm. mesouviformis* were 98.7% identical and claimed that this similarity supports the reduction in status of *Thermomonospora mesouviformis* to a subjective synonym of *Tm. alba*, which was already proposed by McCarthy and Cross (1984a) on the basis of phenotypic study. However, McCarthy and Cross did not validate this proposal. In contrast, Kurup (1979) and Cross (1981) found similarities between *Tm. alba* and *Tm. fusca*, and they argued on their findings that these two species were synonymous but distinct from the mesophilic *Tm. mesouviformis* described by Nonomura and Ohara (1974). In addition, the results of these studies showed that the value of physiological properties for the classification of members of thermophilic actinomycetes including *Thermobifida* is limited. This is probably due to the fact that members of this genus are rather difficult to cultivate and in many cases yield poor inocula (Greiner et al., 1987) or because temperature change affects growth negatively during plating (R.M. Kroppenstedt and L. I. Evtushenko, personal observation). Taking into account these data and the limited usefulness of high 16S rRNA gene sequence similarity for differentiating species (Stackebrandt and Goebel, 1994a), the relationship of *Thermomonospora alba* and *Thermomonospora mesouviformis* species has to be proven by DNA/DNA hybridization.

Streptomonospora salina

The taxonomy of genera comprising the family Nocardiopsaceae is a good example of the dependence of the methods used in systematics in the past for classification of the actinomycetes. With the spread of molecular biological methods like 16S rRNA gene sequencing and the application of polyphasic taxonomy, classification became more and more stable and reliable. Recently the third genus of the family Nocardiopsaceae, *Streptomonospora*, was described. The classification was based on phylogenetic and

phenotypic data (Cui et al., 2001). The only strain of this genus, *Streptomonospora salina* DSM 44593^T (CCTCC 99003^T), was isolated from a salt lake in China. *Streptomonospora salina* DSM 44593^T forms short spore chains on aerial mycelia and single spores on substrate mycelia. The substrate spores are produced singly on branched or simple sporophores, as can be observed in some *Thermobifida* strains. Results from analysis of *Streptomonospora salina* cell walls revealed an unusual combination of amino acids, i.e., *meso*-DAP, glycine, lysine, aspartate, and a trace of LL-DAP. Glucose, galactose, ribose, xylose, arabinose and mannose were detected in its whole cell hydrolysates. The phospholipid pattern was of the PII type and the major menaquinones were represented by MK-9(H₆), MK-10(H₂), and MK-10(H₄).

Habitat

Nocardiopsis

The first description of *Nocardiopsis dassonvillei* (*Streptothrix dassonvillei*) was based on strains isolated from mildewed grain and fodder (Brocq-Rousseau, 1904). Later studies showed that the natural habitat of *Nocardiopsis* is soil. In screening programs searching for new antimicrobial products or other metabolites, members of this genus are frequently isolated from different soils together with streptomycetes and some other actinomycetes (Dolak et al., 1980, 1981; Mikami et al., 1982; Mishra et al., 1987a; Al-Tai and Ruan, 1994; Jiang and Xu, 1998; Wang et al., 1999; Evtushenko et al., 2000; Xu et al., 2001).

Nocardiopsis species were also found in an Antarctic glacier (Abyzov et al., 1983), marine sediments (Dixit and Pant, 2000a; Evtushenko et al., 2000), actinorhizal plant rhizosphere (Boivin-Jahns et al., 1995), gut tract of animals (Vasanthi et al., 1992), as an endophyte of yam bean (Stamford et al., 2001), salterns (Chun et al., 2000), and active stalactites (Laiz et al., 2000). Lacey (1977) detected *N. dassonvillei* strains in cotton waste and occasionally in hay, whereas Mishra et al. (1988) isolated 22 *Nocardiopsis* strains from soil samples. In a study of actinomycetes from indoor environments, toxigenic strains of the two new species *N. exhalans* and *N. umdischolae* were isolated from the water-damaged building material of a children's day care center (Peltola et al., 2001), *N. dassonvillei* from air of a cattle barn using an Anderson sampler (Andersson et al., 1998), and *Nocardiopsis compostus* from the atmosphere of a composting facility (Kämpfer et al., 2002). This strain could grow at temperatures up to 50°C but grew optimally at 30°C. Information on true thermophilic

Nocardiopsis strains is rare. Nearly all *Nocardiopsis* species that have been validly described until now were found at sites with moderate temperatures. The thermotolerant strains (which may grow up to 42°C or even at 50°C) have their optimal growth temperature at 28°C (Evtushenko et al., 2000; Kämpfer et al., 2002) or, in the case of *Nocardiopsis kunsanensis*, at 37°C (Chun et al., 2000). There is only one report of a thermophilic *Nocardiopsis* isolate, KMD/8, that grows up to 65°C with an optimal growth temperature of 50°C (Kempf, 1995). This strain was among 176 thermophilic strains isolated (on glycerol-asparagine-propionate agar at 45°C) from municipal waste compost produced by a compost plant in Germany. Cryophilic *Nocardiopsis* strains were not isolated until now. Abyzov et al. (1983) found a single *Nocardiopsis* strain in an Antarctic glacier at a depth horizon of 85 m, which corresponded to an age of over 2000 years. He named this isolate “*N. antarcticus*,” reflecting its origin. Although this culture was isolated from a cold region, it is a mesophilic species with an optimal growth temperature of 28°C and an inability to grow at 4°C. This species was later reclassified by Yassin et al. (1997), who could show that *N. antarcticus* was a subjective synonym of *N. dassonvillei* subsp. *dassonvillei*.

Members of this genus have been frequently isolated from areas with high salt concentrations, such as *Nocardiopsis lucentensis* from a salt marsh soil sample near Alicante, Spain (Yassin et al., 1993), *Nocardiopsis halotolerans* strain from the same environment at Al-Khiran, Kuwait (Al-Zarban et al., 2002), *Nocardiopsis halophila* from a saline soil sample in Iraq (Al-Tai and Ruan, 1994), and *Nocardiopsis kunsanensis* from a saltern in the Republic of Korea (Chun et al., 2000). Although these species are able to grow at high salt concentration (up to 10–20% NaCl) in medium, only *Nocardiopsis kunsanensis* was classified originally with moderately halophilic actinomycetes (Chun et al., 2000) in accordance with the scheme of Larsen (1986). The optimal growth of this strain was at 5–15% NaCl and it was unable to grow on medium without salt. The minimal NaCl concentration for growth was 3% and the maximum 20%, but sometimes growth could be obtained at 25% depending on culture conditions (Chun et al., 2000). Three other species may be classified as halo tolerant because the same growth can be obtained in the medium without salt. *Nocardiopsis lucentensis* and *Nocardiopsis halophila* were also cited as moderately halophilic species (Ventosa et al., 1998), in accordance to the most widely used classification of Kushner (1978). Their optimal NaCl concentration for growth was 5–10% and 15%, respectively. *Nocardiopsis halophila* did not grow at all in medium contain-

ing less than 5% NaCl (Al-Zarban et al., 2002). It should be pointed out that the salt requirement and tolerance of many bacterial species vary according to growth conditions such as temperature and medium composition (Ventosa et al., 1998).

In a screening program for alkaliphilic bacteria from soils, Mikami et al. (1982) isolated 20 actinomycetes that grew at pH 11.5. Nine of these isolates resembled *N. dassonvillei* morphologically and had the same III/C cell wall chemotype. These strains were later classified as *N. dassonvillei* subsp. *prasina* (Miyashita et al., 1984). At the same time, Mikami et al. (1985) screened the 420 International Streptomyces Project (ISP) streptomyces for alkaliphilic strains and found that only six of them were able to grow at a pH of 11.5 or above. Cell wall analyses of the alkaliphilic strains revealed that half of these strains were misclassified. One strain (ISP 5011^T, DSM 40011^T) was later classified as *Amycolata autotrophica* (Lechevalier et al., 1986) and then transferred to the genus *Pseudonocardia* (Warwick et al., 1994). Another strain, ISP 5465^T, DSM 40465^T, was described as *Nocardiopsis albirubida* (Grund and Kroppenstedt, 1989), while *Streptomyces caeruleus* (ISP 5103^T, DSM 40103^T) showed a close relationship to *Saccharothrix* based on chemical markers (Grund, 1987). Tsujibo isolated alkaliphilic strains from soil that grew at pH 10 and were identified as *N. dassonvillei* (Tsujibo et al., 1988).

Jiang and Xu screened for extremophilic actinomycetes at unusual habitats of Yunnan, China (Jiang and Xu, 1998). They isolated 49 actinomycetes from alkaline soils. Nine of them belonged to the genus *Nocardiopsis*, while the remainder were alkaliphilic or alkali tolerant streptomyces. All *Nocardiopsis* strains could grow at extreme alkaline conditions (i.e., pH 12), whereas the alkaliphilic streptomyces were not able to grow at this high pH. Six of the *Nocardiopsis* isolates were obligate alkaliphilic strains because they grew at pH 8–12 but not at pH 7, whereas the remaining three grew at pH 7 but not at pH 6. None of the *Nocardiopsis* isolates were acidophilic, thermophilic or psychrophilic.

On the basis of these findings, it can be concluded that soil is the natural habitat of *Nocardiopsis* species and that mildly alkaline conditions (pH 8) are best for optimal growth of most strains of this genus. For some *N. dassonvillei* strains (Tsujibo et al., 1988) and other species of this genus, i.e., *N. prasina* (Miyashita et al., 1984) and *N. dassonvillei* subsp. *albirubida* (Mikami et al., 1982; Mikami et al., 1985), growth is enhanced at even higher pH values (10). Inoculation of alkaliphilic strains on agar plates at the lowest possible pH for their growth results in

slow growth, which increases as these bacteria change the pH of the plate until it reaches their optimal pH for growth (Horikoshi and Akiba, 1982; Mikami et al., 1985).

The clinical significance of *Nocardiopsis* strains is well documented. Liegard and Landrieu (1911) reported a case of ocular conjunctivitis from which they isolated a bacterium matching the description of Brocq-Rousseau (1904). They called this strain "*Nocardia dassonvillei*" because of its nocardia-like appearance. Later, Erikson (1935) isolated *Nocardiopsis* strains from other clinical material. The clinical importance of *Nocardiopsis* and related organisms has been discussed by Gordon and Horan (1968). They found that 15 of their 26 collection strains were clinical isolates. The authors speculated that similar cultures from other sources might usually be discarded in laboratories as contaminants because of their macroscopic resemblance to cultures of *Streptomyces griseus*, which is one of the most common actinomycetes in the environment. The clinical significance was later confirmed by Ajello et al. (1987), Beau et al. (1999), Sindhuphak et al. (1985), Singh et al. (1991), and Yassin et al. (Yassin et al., 1993; Yassin et al., 1997), who isolated *Nocardiopsis* strains from clinical material. Guignani et al. (1998) and Mordarska et al. (1998) discuss the role of these isolates as the causal agents of disease.

Thermobifida

Thermobifida belongs to the autochthonic microflora of organic materials, which heat up during degradation (self heated), e.g., manure heaps, composts of different kinds, or damp stored hay (Lacey, 1973). Both species of the genus *Thermobifida* are thermophilic. The optimal growth temperature for *Tb. alba* is 40–45°C, whereas *Tb. fusca* grows better at 50–55°C. *Thermobifida* strains are able to secrete a variety of thermostable extracellular enzymes enabling them to become established as dominant populations during high temperature composting of plant residues and other wastes (Fergus, 1964). They are highly cellulolytic (McCarthy, 1987; Ball and McCarthy, 1988) and/or hemicellulolytic (McCarthy et al., 1985; McCarthy et al., 1988), and strains are abundant in mushroom compost (Fergus, 1964; Lacey, 1974; Lacey, 1977; McCarthy and Cross, 1984a, 1984b). Evidence that cellulose decomposition in mushroom compost involves a positive interaction between cellulolytic actinomycetes and certain bacteria (Stanek, 1972) underscores the possibility that natural lignocellulose degradation is the product of interaction between heterogeneous microflora.

Growth of thermophilic actinomycetes in high temperature environments leads to the release of spores that can cause an exogenous allergic alveolitis. This is well documented for *Saccharopolyspora rectivirgula* (Lacey and Crook, 1988b), *Saccharomonospora viridis* (Green et al., 1981), and some *Thermoactinomyces* species (Greiner-Mai, 1988). There is currently no evidence for implicating spores of *Thermobifida* species in such respiratory disorders (Lacey, 1988a), though the cause of mushroom worker's disease, a form of allergic alveolitis, is still a matter for conjecture. Nevertheless, Van den Borgard et al. (1993) and co-workers presumed *Tb. alba* and *Tb. fusca*, along with *Thermomonospora curvata* and misclassified actinomycete "*Excellospora flexuosa*," contribute to the occurrence of "mushroom worker's lung" (MWL) because 1) high numbers of spores of these organisms were present in air breathed by the affected mushroom workers and 2) serum titers of actinomycete spore antibodies were elevated in these workers. Vast numbers of spores of thermophilic actinomycetes, including spores of *Tb. alba* and *Tb. fusca*, were collected from the air in fermentation tunnels during the spawning of mushroom compost. Sera from ten mushroom growers affected by MWL were tested by a qualitative dot-enzyme-linked immunosorbent assay (ELISA) for antibodies against the spores of these micro-organisms. All 10 sera were positive for one or more of the actinomycetes, *Nonomuraea flexuosa* ("Excellospora"), *Tb. alba*, *Tb. fusca* and *Tm. curvata*. In contrast, no antibodies were found against *Streptomyces thermovulgaris*, *Thermoactinomyces vulgaris* and *T. sacchari* or against fungi. Sera of 11 of 14 workers engaged in routine spawning of compost in tunnels reacted positively with one or more of the actinomycetes. Their serum titers increased with the duration of employment to an upper limit of 2.5. The sera of 19 non-exposed individuals were negative.

Streptomonospora

The description of the genus *Streptotomonospora* was based on a single isolate, *Streptotomonospora salina* YIM 90002^T (CCTCC 99003^T, DSM 44593^T; Cui et al., 2001). The strain was isolated from a hypersaline habitat of soil samples collected from a salt lake in Xinjiang, a western province of China, during a taxonomic study on extremophilic actinomycetes. Owing to its optimal growth at 15% NaCl, this strain can be referred to as a moderately halophilic microorganism. Isolation and studies of additional strains of this genus will shed more light on the habitat and occurrence of members of this genus.

Isolation and Cultivation

Nocardiosis

For enrichment and isolation of *Nocardiosis* strains, no specific procedures have been described (Meyer, 1989), and the same methods described for the isolation of streptomycetes can generally be used (Korn-Wendisch and Kutzner, 1992). Good results have been obtained using the GAC-Agar medium of Nonomura and Ohara (Ohara, 1971a; Ohara, 1971b). The following special method for the isolation of alkaliphilic *Nocardiosis* strains has been reported by Horikoshi (1971): a small amount of soil is suspended in 1 ml of sterilized water, 100 µl aliquots of the suspension are spread on dry agar plates and the plates are incubated for 7 to 14 days at 27°C. For isolation of *N. halophila*, the modified complex medium (SGA agar) containing 20% NaCl was used (Al-Tai and Ruan, 1994), and *Nocardiosis kunsanensis* has been isolated on Bennett's agar based on seawater (Chun et al., 2000). Spores or mycelium of isolated colonies are picked up with a needle and streaked on different cultivation media for color determination and for macroscopic, microscopic and chemotaxonomic examination.

Solution A: GAC Agar (Nonomura and Ohara, 1971a; 1971b)

Glucose	1.0 g
L-Asparagine	1.0 g
K ₂ HPO ₄	0.3 g
MgSO ₄ · 7 H ₂ O	0.3 g
NaCl	0.3 g
Trace salts	1.0 ml
Distilled water	1.0 liter
Agar	15.0 g

Solution B:

Casamino acids	0.5 g
Adjust the pH to 8.0 with NaOH solution and autoclave	
Trace salt solution	
FeSO ₄ · 7H ₂ O	10 mg
MnSO ₄ · 7H ₂ O	1 mg
CuSO ₄ · 5H ₂ O	1 mg
ZnSO ₄ · 7H ₂ O	1 mg
Distilled water	1 ml
Adjust the pH to 8.0	

Dissolve solution A components in one liter of distilled water and solution B (casamino acids) in one liter of distilled water and autoclave. Antibiotics (cycloheximide, nystatin, each 50 µg/ml; polymyxin B, 4 µg/ml; and penicillin, 0.8 µg/ml) may be added to autoclaved medium A to the final concentration. Four ml of solution B is poured over 15 ml of hardened agar plates.

Horikoshi Agar for Alkaliphilic *Nocardiosis* Strains (Horikoshi, 1971)

Glucose	10.0 g
Peptone	5.0 g
Yeast extract	5.0 g
K ₂ HPO ₄	1.0 g
MgSO ₄	0.2 g
NaCO ₃	10.0 g
Distilled water	1.0 liter
Agar	20.0 g

Adjust the pH of the autoclaved medium with sterile sodium carbonate to 10.

SGA Agar (Al-Tai and Ruan, 1994)

Casamino acids	7.5 g
Yeast extract	10.0 g
MgSO ₄ · 7H ₂ O	20.0 g
Sodium citrate	3.0 g
KCl	1.0 g
NaCl	200 g
Trace salts	1 ml
Water	1.0 liter
Agar	15.0 g

Trace salt solution:

FeSO ₄ · 7H ₂ O	0.1 g
MnCl ₂ · 4H ₂ O	0.1 g
ZnSO ₄ · 7H ₂ O	0.1 g
Distilled water	100.0 ml

Dissolve all SGA agar components, autoclave and adjust to pH 7.5.

Bennett's Agar Based on Seawater (Chun et al., 2000)

Glucose	2.0 g
Malt extract	1.0 g
Yeast extract	1.0 g
Peptone	2.0 g
Sea water	1 liter
Agar	20.0 g

Dissolve all ingredients, autoclave and adjust to pH 7.2.

Most *Nocardiosis* species grow very well at 28°C on agar media used in the ISP (Shirling and Gottlieb, 1966). After 14–21 days of incubation at optimal conditions, the colour of the white aerial mycelia will change to yellow or gray, indicating the production of spore chains. For optimal growth of *N. alba* and some *N. dassonvillei* strains, the pH of the ISP media should be adjusted to pH 8.5 with sterile sodium carbonate after autoclaving. Although *N. listeri* grows quite well on the ISP media, no aerial mycelia are produced. Hickey-Tresner agar (Hickey and Tresner, 1952) is the only medium where sparse white aerial mycelia are seen. The truly alkaliphilic species, i.e., *N. dassonvillei* subsp. *albirubida* and *N. prasina*, need an even higher pH of 10 to produce aerial mycelia and spores on yeast-extract malt-extract agar. The pH has to be adjusted to 10 or above with sodium hydroxide

after autoclaving. However, some of the strains can produce aerial mycelia and spores on ISP medium 3 (oatmeal agar) at pH 8.0. The halotolerant or moderately halophilic species, *Nocardiopsis halophila* and *Nocardiopsis kunsanensis*, grow optimally on most ISP media in the presence of 5–15% NaCl (Chun et al., 2000). Also, 5–10% NaCl should be added for optimal growth of *Nocardiopsis lucentensis* (Ventosa et al., 1998). The following media are used for cultivating most species of the genus *Nocardiopsis*:

ISP Medium 2: Yeast Extract Malt Extract Agar (Pridham et al., 1956–1957)

Yeast extract (Difco)	4.0 g
Malt extract (Difco)	10.0 g
Dextrose	4.0 g
Agar	20.0 g
Distilled water	1.0 liter

Dissolve and autoclave.

ISP Medium 3: Oatmeal Agar (Küster, 1959b)

Oatmeal	20.0 g
Agar	18.0 g
ISP-Trace salt solution:	
FeSO ₄ · 7H ₂ O	0.1 g
MnCl ₂ · 4H ₂ O	0.1 g
ZnSO ₄ · 7H ₂ O	0.1 g
Distilled water	100.0 ml

Cook or steam 20g of oatmeal in 1 liter of distilled water for 20 minutes. Filter through cheesecloth. Add distilled water to restore volume of filtrate to 1 liter. Add salt solution. Adjust to pH 7.5 with NaOH. Add 18g of agar; liquefy by steaming at 100°C for 15–20 min.

ISP Medium 4: Inorganic Salts-starch Agar (Küster, 1959a)

Solution I:
Difco soluble starch 10.0 g
Make a paste of the starch with a small amount of cold distilled water and bring to a volume of 500 ml.

Solution II:	
K ₂ HPO ₄ (anhydrous)	1.0 g
MgSO ₄ · 7H ₂ O	1.0 g
NaCl	1.0 g
(NH ₄) ₂ SO ₄	2.0 g
CaCO ₃	2.0 g
Distilled water	500 ml

ISP-trace salt solution (see ISP medium 3) 1.0 ml

Adjust to pH 7.5. Mix solutions I and II together. Add 20 g of agar. Liquefy agar by steaming at 100°C for 10–20 min.

ISP Medium 5: Glycerol-asparagine Agar (Pridham et al., 1956–1957)

L-asparagine (anhydrous)	1.0 g
Glycerol	10.0 g
K ₂ HPO ₄ (anhydrous)	1.0 g
Distilled water	1.0 liter
ISP-trace salt solution	1.0 ml
Agar	20 g

Dissolve (and add trace salts [see ISP medium 3 above]) and adjust to pH 7.4.

ISP Medium 7: Tyrosine Agar Medium (Shinobu, 1958)

Glycerol	15.0 g
L-Tyrosine	0.5 g
L-Asparagine	1.0 g
K ₂ HPO ₄ (anhydrous)	0.5 g
MgSO ₄ · 7H ₂ O	0.5 g
NaCl	0.5 g
FeSO ₄ · 7H ₂ O	0.01 g
Distilled water	1.0 liter
Trace salt solution	1.0 ml
Agar	20 g

Dissolve all ingredients (and add trace salt [see ISP medium 3 above]) and adjust to pH 7.5.

Hickey-Tresner Agar Medium (Hickey and Tresner, 1952)

Dextrin	10.0 g
Tryptone	2.0 g
Meat extract	1.0 g
Yeast extract	1.0 g
CoCl ₂	2.0 g
Agar	15.0 g
Distilled water	1.0 liter

Dissolve and adjust to pH 7.5 and autoclave.

Thermobifida

Good sources for the isolation of *Thermobifida* strains are composted horse manure/straw (the so-called “mushroom compost”; Fergus, 1964), bio-composted paper (Kempf, 1995), municipal solid waste compost (Stutzenberger, 1971; Rész et al., 1977), or self-heated grass clippings (Kutzner, 2000). *Thermobifida* dominate the microflora in these habitats owing to their high cellulolytic activity. For the isolation of the actinomycetes, 1 g of air-dried sample is suspended in 100 ml of Ringer’s solution and mixed with 10 g of sterile plastic beads. The sample is shaken at 180 rpm for 30 min to release the spores and mycelia from the compost particles. Subsequently, 0.1 ml of a decimal dilution series is plated on pre-dried starch-casein-KNO₃-agar plates. The Petri dishes should be pre-dried to reduce the swarming of *Bacillus* isolates. For reduction of the accompanying bacteria and fungi, Na-propionate (4 g/liter) is added (Lacey, 1974). However, the addition of Na-propionate results in the reduction of aerial mycelia of actinomycetes. Half -strength nutrient agar appears to be a good medium for *Thermobifida* strains.

Minimal salt-yeast extract nutrient medium (Ramachandra et al., 1988) supplemented with different carbon sources was shown to be good for stimulating the production of extracellular lignocellulose-degrading enzymes, e.g., endo-1,4-β-xylanase, endo-1,4-glucanase, and peroxidase, in *Thermobifida fusca*. The highest production of these enzymes was found at 50°C and pH 8 under high aeration and when the medium was supple-

mented with oat spelt xylan or ball-milled wheat straw. The highest activities of endoxylanase, endoglucanase, peroxidase, β -xylosidase, and α -L-arabinofuranosidase were detected on 0.6% or 0.8% (w/v) xylan, which corresponds to C:N ratios of 4:1 and 5.3:1, respectively. Straw 0.8% (w/v) was also a good growth substrate for the production of endoxylanase and endoglucanase, while peroxidase activities reached the highest level on 0.6% (w/v) straw. Maximum production of β -xylosidase and α -L-arabinofuranosidase was detected on 0.4% (w/v) straw (Tuncer et al., 1999).

Modified Starch-Casein-KNO₃-Agar (Küster and Williams, 1964, modified)

Starch (soluble)	10.0 g
Casein	0.3 g
KNO ₃	2.0 g
KH ₂ PO ₄	0.3 g
K ₂ HPO ₄	0.7 g
MgSO ₄ · 7H ₂ O	0.5 g
NaCl	1.0 g
Trace elements solution	5.0 ml
Distilled water	1 liter

Trace Elements Solution SPV-4 (Voelskow, 1988)

CaCl ₂ · 2H ₂ O	4 g
Fe-III-citrate	1 g
MgSO ₄	200 mg
ZnCl ₂	100 mg
CuSO ₄ · 5H ₂ O	40 mg
CoCl ₂ · 6H ₂ O	22 mg
Na ₂ MoO ₄ · 2H ₂ O	25 mg
Na ₂ B ₄ O ₇ · 10H ₂ O	100 mg
Water	1 liter

Adjust pH of the trace elements solution and modified starch-casein-KNO₃ to 7.2. Add 12g of agar.

Nutrient agar (1/2 conc.)

Peptone from casein	2.5 g
Meat extract	1.5 g
Distilled water	1 liter

Adjust to pH 7.2. Add 12g of agar.

Minimal Salt-Yeast Extract Nutrient Medium (Ramachandra et al., 1988)

Glucose	6.0 g
Yeast extract	0.1 g
(NH ₄) ₂ SO ₄	0.1 g
NaCl	0.3 g
MgSO ₄	0.1 g
Ca ₂ CO ₃	0.02 g
Trace elements solution SPV-4	1 ml
Water	1 liter
Trace elements solution	
Fe ₂ (SO ₄) ₃	1.0 g
ZnSO ₄	0.9 g
MgSO ₄	0.2 g
Water	1 liter

Adjust pH of the trace elements solution and minimal salt-yeast extract nutrient medium to 8.0 and autoclave.

Streptomonospora

Soils or other samples collected in areas with high salt concentrations may be sources for the

isolation of halophilic or halotolerant strains of the genus *Streptomonospora* (Cui et al., 2001). Media supplemented with salt, e.g., the modified medium ISP 5, may be used for isolation of *Streptomonospora* (Cui et al., 2001).

Modified ISP Medium 5 for Isolation of *Streptomonospora salina* (Cui et al., 2001)

L-Asparagine (anhydrous)	1.0 g
Glycerol	10.0 g
K ₂ HPO ₄ (anhydrous)	1.0 g
NaCl	150 g
Distilled water	1.0 liter
Trace salt solution	1.0 ml
Water	1 liter

Adjust to pH 7.0. Add 20 g of agar.

Streptomonospora salina grows very well at 28°C on most agar media used in the ISP (Shirling and Gottlieb, 1966). Only ISP medium 3 (oatmeal agar) does not support growth. Optimum growth occurs in media with salt at a concentration of 15% and pH 7.0 (Cui et al., 2001).

Identification

New micro-organisms can be identified as members of the family Nocardioptaceae by both 16S rRNA gene analysis and phenotypic studies. The 16S rRNA gene sequences (full or partial sequences of about the first 500 nucleotides) of *Nocardioptis*, *Thermobifida* and *Streptomonospora* are specific, and strains of these genera form closely aggregated clades (Rainey et al., 1996; Zhang et al., 1998; Cui et al., 2001). Many *Nocardioptis* isolates or respective DNA samples may be also identified by the signature nucleotides from positions 1435 to 1466 of the *E. coli* numbering system of Brosius et al. (1978; Rainey et al., 1996). However, in order to affiliate new isolates to *Nocardioptis*, *Thermobifida*, *Streptomonospora* or new genera, morphological and chemotaxonomic characteristics should be examined (Table 3). Identification of new strains at the species level requires additional phenotypic studies and in some cases determination of DNA/DNA relatedness. The phenotypic characteristics useful for identification of members of the family Nocardioptaceae at different taxonomic levels and different approaches to identification based on these characteristics are given in the following sections.

Nocardioptis

DIFFERENTIATION OF THE GENUS *NOCARDIOPTIS* FROM OTHER GENERA *Nocardioptis* isolates can be differentiated from all other actinomycetes by a combination of phenotypic and chemotaxonomic markers. Although *Nocardioptis* resem-

Symbols: see footnote in Table 2.

Abbreviations: AM, aerial mycelium; SM, substrate mycelium; Gly, glycine; Asp, aspartate; DAP, diaminopimelic acid; (LL-DAP), trace of LL-DAP; n.d., not determined; and see footnote in Table 3 for other definitions.

^aNon-fragmenting hyphae may be present in some species.

^bAlanine and glutamate are present in all genera.

^cTeichoic acids are present, and glycerol or other main constituents of these polymers are determined in the cell wall (Naumova et al., 2001; see also Table 6).

^dGlucose (39%), galactose (34%), ribose (15%), xylose (6%), arabinose (5%), and mannose (2%) were determined in whole cell hydrolysates.

Adapted from McCarthy and Cross (1984a); Grund and Kroppenstedt (1990); Yassin et al. (1993); Chun et al. (2000); Evtushenko et al. (2000); Cui et al. (2001); and Naumova et al. (2001).

bles many other actinomycetes morphologically (e.g., the presence of long sporulated aerial hyphae and fragmenting substrate mycelia), it shows quite specific chemical signatures (Tables 3 and 4). *Nocardioseae* has a cell wall chemotype III/C, i.e., 2,6-*meso*-diaminopimelic acid, alanine, and glutamic acid in its peptidoglycan. The muramic acid of the peptidoglycan is acetylated (Kroppenstedt, 1987). In whole cell hydrolysates, glucose and galactose are also detected (type C). Diagnostic sugars, like arabinose, madurose, xylose or rhamnose, are absent (Lechevalier and Lechevalier, 1970b; Grund and Kroppenstedt, 1990; Yassin et al., 1993, 1997; Al-Tai and Ruan, 1994; Chun et al., 2000; Evtushenko et al., 2000; Naumova et al., 2001). Cell wall teichoic acids are present and composed of glycerol and other main constituents, like ribitol, glucosamine, galactosamine, succinic and propionic acids. Different *Nocardioseae* species are determined by the cell wall teichoic acid composition (Naumova et al., 2001).

No mycolic acids are present in whole cell methanolsates (Mordarska et al., 1972; Minnikin et al., 1975). The phospholipid pattern is composed of phosphatidylcholine (cardiolipin), phosphatidylmethylethanolamine (PME), phosphatidylglycerol (PG), phosphatidyl inositol

(PI), and small amounts of diphosphatidylglycerol (DPG). In addition, two spots of glycolipids identified as monomannosyl diglyceride and monoacetylated glucose (Mordarska et al., 1983) and 2–4 unknown phospholipids that run above the DPG spot are detected on two-dimensional thin layer chromatography (TLC)-plates (Minnikin et al., 1977; Grund and Kroppenstedt, 1990; Fig. 2). The occurrence of phosphatidylcholine in lipid extracts of *Nocardioseae* corresponds with phospholipid type III, according to Lechevalier et al. (1977). *Nocardioseae* synthesizes menaquinones with an isoprene side chain of 10 units. Depending on the species up to four of these isoprene units are saturated, i.e., MK-10(H₀) to MK-10(H₈). Small amounts of the MK-9 series are also found (Minnikin et al., 1978; Fischer et al., 1983; Grund and Kroppenstedt, 1990; Fig. 3).

Members of this genus are characterized by terminally branched and 10-methyl-branched fatty acids showing a chain length of 14 to 18 carbon atoms. Hydroxy fatty acids have never been detected in *Nocardioseae* strains (Grund and Kroppenstedt, 1990). Among the terminally branched fatty acids, 14-methyl-heptadecanoic acid (*iso*-16:0; 21–35%) and 14-methyl-hexadecanoic acid (*anteiso*-17:0; 7–24%) are the main components. Substantial amounts (6–18%)

Table 4. *Footnote continued*

Abbreviations: n. d., not determined; n. c., not characteristic; Rham, rhamnose; Ara, arabinose; Gal, galactose; Mad, madurose (3-*O*-methylgalactose); Xyl, xylose; PC, phosphatidylcholine; PME, phosphatidylmethylethanolamine; GL, glycolipid; PI, phosphatidylinositol; PG, phosphatidylglycerol; OH-PE, hydroxy-phosphatidylethanolamine; DPG, diphosphatidylglycerol; PIMs, phosphatidyl-*myo*-inositol mannosides; and PGN, phosphatidylglucosamine.

^aCell wall types are given in H. A. Lechevalier and M. P. Lechevalier (1970a, b); cell wall types correspond to the following peptidoglycan types: I, A3 gamma; and II, III, and IV, A1 gamma (Schleifer and Kandler, 1972).

^bDiagnostic sugars may be present, but have no taxonomic implication in cell wall type 1^c. Ribose (Rib) reported for some species is usually determined in whole cell hydrolysates of all actinomycetes.

^cWhole cell sugar types given in M. P. Lechevalier and H. A. Lechevalier (1970a, b).

^dGlycerol and/or ribitol present if cell wall contains teichoic acids.

^ePhospholipid types according to Lechevalier et al. (1977).

^f10/4, MK-10 (H₄), i.e., a menaquinone having 10 isoprene units, two of which are saturated.

The principal menaquinones with different degree of saturation are characteristic for different *Nocardioptosis* species (see Table 6).

For *Streptoalloteichus*, *Actinopolyspora* and *Catenuloplanes*, the following major menaquinones were also reported: 10/4, 10/6; 9/4, 10/4; and 9/8, 10/8, respectively (Tamura et al. 2000b). In *Saccharopolyspora halophila*, menaquinones 9/6 and 9/8 were determined (Lu et al., 2001).

^gMenaquinone types according to Kroppenstedt (1985) are exemplified as follows: type 1, no hydrogenation of the isoprenoid chain, e.g., MK-9; type 2, only one menaquinone present, di- or tetrahydrogenated, e.g., MK-9(H₄); type 3, a tetrahydrogenated multiprenyl menaquinone, e.g., MK-9(H₄) and MK-10(H₄); type 4, menaquinones with the same isoprenoid chain length but increasing degree of hydrogenation, e.g., MK-9(H₄), and MK-9(H₈); positions of double bonds in isoprenoid chains are diagnostic, e.g., MK-9(II,III-H₄) vs. MK-9(III,VIII-H₄) 4A1 vs. 4A2; and MK-9(II,III,IX-H₄) vs. MK-9(II,III,VIII-H₄) 4B1 vs. 4B2. From Batrakov and Bergelson (1978); Yamada et al. (1978a, b); Howard, et al. (1986); Collins and Kroppenstedt (1987); and Collins et al. (1988).

^hFatty acid types according to Kroppenstedt (1985); for further information, see Table 11. Fatty acid type 2c was also reported for *Actinopolyspora* and *Saccharopolyspora* (Tamura et al., 2000b).

ⁱMotile spores are formed in aqueous environment.

^jNo aerial mycelium was observed; rhamnose and 3-*O*-methylrhamnose may be present in cell wall of some species.

^kAerial mycelium is rudimentary, developed or absent; the spore chains are aggregated into clusters and may be developed by outer sheaths.

^lSporangiospores are found in addition.

(1993, 1999); Tomita et al. (1993); Yassin et al. (1993, 1997); Al-Tai and Ruan (1994); Tamura et al. (1998, 2000a, b); Zhang et al. (1998, 2001); Chung et al. (1999); Park et al. (1999); Chun et al. (2000); Labeda and Kroppenstedt (2000); Lee et al. (2000); Lu et al. (2001); and Naumova et al. (2001).

Fig. 2. Two-dimensional thin layer chromatograms of polar lipids of *Nocardiopsis dassonvillei* DSM 43111 and *N. listeri* DSM 40297. Abbreviations: DPG, diphosphatidylglycerol; PME, phosphatidylmethylethanolamine; PG, phosphatidylglycerol; PC, phosphatidylcholine; PI, phosphatidylinositol; PIM, phosphatidylinositolmannosides; AG, monoacetylated glucose; MDG, monomannosyl diglyceride; PL, unknown phospholipids specific for *Nocardiopsis*; ? Lipids of unknown structure.

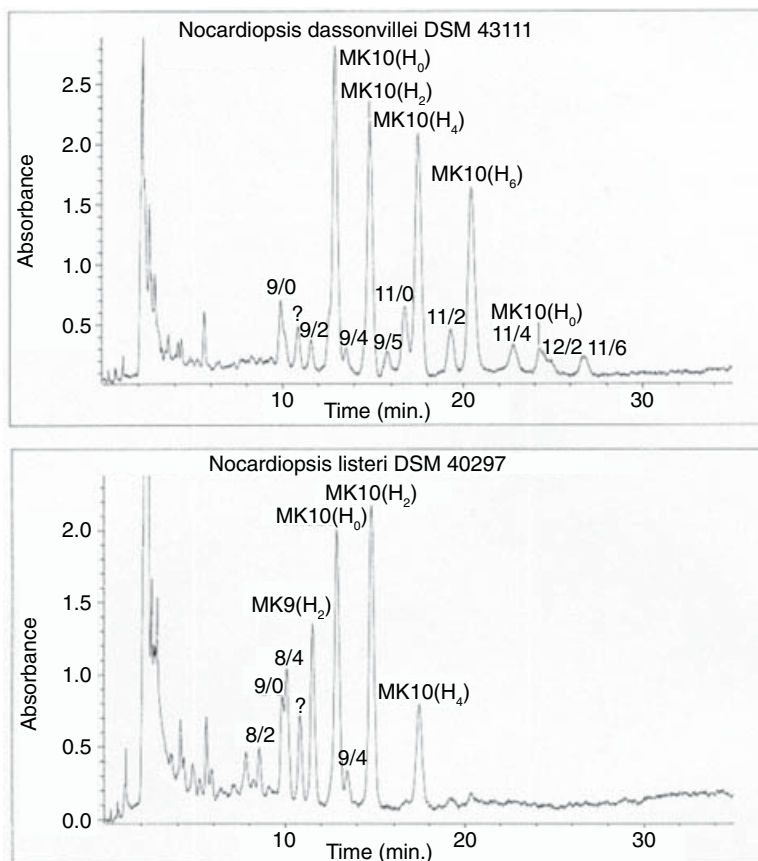

Fig. 3. Menaquinone profiles of *Nocardiopsis dassonvillei* (top) and *N. listeri* (bottom). The extent of hydrogenation of the 10 isoprene units is shown by the subscript of the abbreviation. For instance, MK-10(H₈) is a menaquinone with four hydrogenated isoprene units. Injection volume 5 µl; 5% of the extract prepared by the method of Minnikin et al (1984) without further purification.

of the 10-methyl branched tuberculostearic acid, i.e., 10-methyl-octadecanoic acid (10-methyl-18:0), and its precursor the unsaturated *cis* 9,10 octadecenoic acid (18:1 *cis*; 2–19%) have been found in addition (Grund and Kroppenstedt, 1990). According to Kroppenstedt (1985), this fatty acid pattern belongs to fatty acid type 3d. Table 5 lists the fatty acid types found among Actinomycetales. They can be combined into 3 main types and 14 subtypes (diagnostic fatty acids of the main types in bold). Type 1 is characterized by unbranched saturated and unsaturated fatty acids and those fatty acids for which unsaturated fatty acids are precursors, i.e., cyclopropane and 10-methyl-branched fatty acids. Type 2 is composed of *iso*- and *anteiso*-branched fatty acids. In type 3, both types, (the terminally branched [*iso/anteiso*] and the 10-methyl-branched fatty acids) are present. Subtypes of types 2 and 3 are mainly based on quantitative differences of the fatty acids and the occurrence of hydroxy fatty acids.

PRESUMPTIVE IDENTIFICATION OF *NOCARDIOPSIS* STRAINS BASED ON MORPHOLOGY Although *Nocardiopsis* strains resemble many other actinomycetes morphologically, their specific macroscopic and microscopic features may be used for presumptive identification. Members of this genus produce sparse-to-abundant white aerial mycelia that in most species become yellow-gray (griseus-colored) during spore formation. The aerial hyphae are long, moderately branched, straight to flexuous. They show a typical zig-zag formation before spore delimitation. The elongated smooth spores differ in length and can divide subsequently into smaller spores of irregular size. Spores are enclosed within a fibrillar sheath and have thickened polar walls.

Although many *Nocardiopsis* strains resemble *Streptomyces griseus* or other streptomycete strains macroscopically (Gordon and Horan, 1968; Shirling and Gottlieb, 1972), the two genera can be differentiated by their specific type of spore formation and spores (Table 2). In contrast to *Streptomyces* where spores of the same shape are delimited basipetally almost simultaneously, in *N. dassonvillei*, the cross walls are formed in a relatively uncoordinated manner resulting in spores of various lengths. *Actinomadura* (including the species currently belonging to *Nonomuraea*, *Saccharothrix* and *Lechevalieria*) has also been mixed up with *Nocardiopsis* (Table 1). However, *Nocardiopsis* differs from these genera in morphology and the specific mode of spore formation. In *Actinomadura* and *Nonomuraea*, special spore-forming hyphae develop on sterile aerial mycelia, either singly or in clusters, producing short chains of spores showing hooks or spirals with 1.5 to 2 turns, whereas in *Nocardiop-*

sis, special spore-forming hyphae are absent. In this latter genus, the straight, spiralled aerial mycelium disintegrates completely into fragmentation spores (Table 2). However, it is quite difficult to differentiate *Nocardiopsis* from *Glycomyces harbinensis* and *Glycomyces rutgersensis* on morphological characters alone. Slight differences may be found in the formation of substrate and aerial mycelia between them. Labeda et al. (1985) reported stable substrate mycelia and scant aerial mycelia carrying short chains of square-ended conidia in *Glycomyces* species, whereas in many *Nocardiopsis* strains, the substrate mycelium fragments very early depending on strain and culture conditions. In addition, most strains of *Nocardiopsis* develop abundant aerial mycelia with long hyphae that fragment completely into chains of conidiospores (Meyer, 1989). Similarities also occur in morphology between *Nocardiopsis* and *Saccharothrix*, *Lentzea*, and *Lechevalieria* (Labeda et al., 1984, 2001; Labeda, 1992). At the macroscopic and microscopic levels, no clear dissimilarities may be observed between the *Nocardiopsis* strains and some representatives of the genera *Amycolatopsis* (Lechevalier et al., 1986; Mertz and Yao, 1993), *Kitasatospora* (Chung et al., 1999) or other actinomycetes exhibiting long spore chains and the fragmented vegetative mycelium.

RAPID IDENTIFICATION OF THE GENUS *NOCARDIOPSIS* FROM OTHER GENERA BASED ON PHOSPHOLIPID PATTERN AND MAJOR CONSTITUENTS OF CELL WALL A rapid diagnosis for reliable differentiation of *Nocardiopsis* strains from all other actinomycete taxa is based on their specific phospholipid pattern type III, and in some cases, on the diagnostic diamino acid or sugars arabinose and galactose determined in whole cell hydrolysates (Table 3). Besides *Nocardiopsis*, only a few actinomycete genera, namely, *Kribella*, *Hongia*, *Kineosporia*, *Catenuloplanes*, *Actinopolyspora*, *Pseudonocardia* and *Saccharopolyspora*, show the same phospholipid type, with phosphatidylcholine as main diagnostic component. The *Nocardiopsis* strains can be easily separated from the first four genera by the presence of *meso*-DAP in their whole cell hydrolysates, and they are differentiated from *Pseudonocardia*, *Actinopolyspora*, and *Saccharopolyspora* by absence of arabinose and galactose in whole cell hydrolysates, presence of glycerol or ribitol in the cell wall, or by additional lipid markers.

ADDITIONAL LIPID MARKERS: INFORMATION FOR THE GENERIC LEVEL IDENTIFICATION OF THE GENUS *NOCARDIOPSIS* BY LIPIDS The *Nocardiopsis* strains synthesize phospho- and glycolipids

^aDiagnostic fatty acids of main types are emphasized by blue bold and enlarged crosses, those of subtypes by green bold crosses, i.e., type 1, straight chain saturated and unsaturated fatty acids; type 2, *iso/anteiso*-branched fatty acids; type 3, *iso/anteiso*-branched fatty acids plus 10-methyl-branched fatty acids.

^bExcept *C. ammoniagenes*, *C. bovis*, *C. minutissimum*, *C. pilosum* and *C. variabilis* which belong to type 1b.

^cIncluding *Dietzia*, *Gordonia*, *Mycobacterium*, *Rhodococcus*, *Skermania*, *Tsukamurella* and *Williamisia*.

^dOccurrence of hydroxy fatty acids is species specific among Streptomyces. Branched 2-hydroxy fatty acids could be found in all tested strains of *S. coelicolor* (30 strains), *S. rimosus* (14 strains), *S. violaceusniger* (18 strains) and in 20 of 27 strains of *S. hygroscopicus*. No hydroxy fatty acids could be detected in *S. albus* (33 strains), *S. fradiae* (25 strains), *S. glaucescens* (8 strains), *S. griseus* (22 strains), *S. violaceoruber* (16 strains), *S. viridochromogenes* (25 strains).

From Kawanami et al. (1969) and Y. Zhang and R. M. Kroppenstedt (unpublished observations).

that are not found in *Pseudonocardia*, *Actinopolyspora*, and *Saccharopolyspora*, which also contain meso-DAP in their cell walls. Separating the lipid extract on TLC plates using the solvent system of Minnikin et al. (1984), 3–4 additional unidentified phospholipids (PL) with high R_f values above diphosphatidylglycerol (DPG) and two glycolipids (monomannosyl diglyceride and monoacetylated glucose) right below phosphatidyl methylethanolamine (PME) can be detected on TLC plates (Minnikin et al., 1977; Grund, 1987; Mordarska et al., 1998; Fig. 2).

In addition, these three genera with the above listed phospholipid type III may be further differentiated from *Nocardiopsis* by looking for specific phospholipids containing primary or secondary amino groups, i.e., phosphatidylethanolamine (PE), PME, hydroxy-PE and lyso-PE, (1) PME and lyso-PE in *Saccharopolyspora* species, (2) PE, lyso-PE, hydroxy-PE in *Pseudonocardia* and (3) PE in *Actinopolyspora*. In *Nocardiopsis*, only one ninhydrin-positive spot, PME, is present.

Nocardiopsis species show complex menaquinone patterns containing menaquinones from MK-10 to MK-10(H₈) (Fig. 3, Table 4). Small amounts of the MK-9 and/or MK-11 series are also found. Although the major menaquinones of MK-10 series are found in some other conidia- and arthrospore-forming actinomycetes, the latter can be distinguished because here MK-10(H₄), MK-10(H₂) or MK-10(H₆) usually occurs in different combinations, together with MK-9(H₄) as in *Saccharopolyspora* and *Saccharothrix*, MK-9(H₆) as in *Streptomonospora*, or high amounts of MK-10(H₈) and MK-11(H₆) as in *Thermobifida* strains or MK-11(H₄) typical of *Catenuloplanes* (Kudo et al., 1999). Only *Herbidospira* and *Spirilliplanes* were reported to contain the major menaquinone MK-10(H₄), along with other minor components of MK-10 series, e.g., MK-10(H₂) and MK-10(H₆) or MK-10(H₂) and MK-10(H₈) (Kudo et al., 1993; Tamura et al., 1997). However, these genera can be differentiated easily from *Nocardiopsis* spp. by morphology, polar lipids, and cell wall and fatty acid composition.

The fatty acid pattern is a significant taxonomic marker in *Nocardiopsis*. *Nocardiopsis* strains are easily separated from all other actinomycetes on the basis of their specific fatty acid patterns (Fischer et al., 1983; Poschner et al., 1985; Tables 3 and 4). For differentiation from other taxa, both qualitative and quantitative differences of the fatty acid patterns are useful (Grund and Kroppenstedt, 1989, 1990).

DIFFERENTIATION OF *NOCARDIOPSIS* SPECIES
Nocardiopsis species may be differentiated from each other by comparing the occurrence of aerial

mycelia, morphology, color of substrate and aerial mycelia, pattern of carbon-source utilization and growth at different pH, salt concentrations and temperatures (Table 6). Most *Nocardiopsis* species produce white aerial mycelia, which become yellowish grey (griseus color) after 2–3 weeks. On specific media, the white aerial mycelia of some *Nocardiopsis* develop shades of different colors with age, e.g., *N. prasina* develops, on mineral starch agar and oat meal agar, a leek-green aerial mycelium; colonies of *N. dassonvillei* subsp. *albirubida* turn grey after 3–4 weeks. *Nocardiopsis listeri* fails to produce any aerial mycelia at all on nearly all media. The reverse sides of most *Nocardiopsis* colonies show no specific colors. Some show a reddish tone like *N. dassonvillei* subsp. *albirubida* (brownish-red), *N. halophila* (yellow-red), *N. trehalosi* (orange), and *N. synnemataformans* (pimento colored).

Growth on high salt concentration of up to 20% NaCl is of diagnostic value for *N. halophila* and *N. kunsanensis*, whereas *N. prasina* and *N. dassonvillei* subsp. *albirubida* can easily be differentiated from the other *Nocardiopsis* species by their alkaliphilic behavior. They are able to grow at pH up to 12 but not at pH 6. Their optimal pH for growth is pH 10. The other *Nocardiopsis* species prefer mild alkaline condition (pH 7.7–8), but they are able to grow at pH 6. *Nocardiopsis* are mesophilic actinomycetes, which grow best at about 28°C. Some species have an optimum at 37°C (*N. kunsanensis*) or grow up to 42°C, but only *N. trehalosi* is able to grow at 45°C (Table 6).

The menaquinone profiles can also be used for separation of *Nocardiopsis* strains at the species level. In *N. dassonvillei* subsp. *albirubida*, *N. listeri*, and *N. synnemataformans*, the highly saturated MK-10(H₆) and MK-10(H₈) are usually missing. In addition, *N. dassonvillei* subsp. *albirubida* and *N. listeri* synthesize a higher amount of MK-9(H₄) and can be separated from most other *Nocardiopsis* species by this difference (Fig. 3). Exceptions are found in some strains of *N. dassonvillei* subsp. *dassonvillei*. Most strains of this species, together with *N. alba* and *N. prasina*, have predominant menaquinone MK-10(H₄). The major menaquinone components of other species are highly saturated, up to four isoprene units.

Recently, Naumova and coworkers demonstrated that the structures and different combinations of cell wall teichoic acids are useful for differentiation of *Nocardiopsis* species (Naumova et al., 2001). The degradation products of whole cell walls derived from teichoic acids and the ¹³C-NMR spectra of polymers were able to differentiate each of the eight species and subspecies studied (Table 7). These products (glucose, ribitol, glycerol, succinic and propionic

Abbreviations for phospholipid pattern, cell wall chemotype and menaquinones as in table 3.

acids), in some cases combined with the major menaquinones, morphological features and the ability of strains to grow at different conditions, allow one to attribute new strains to the listed *Nocardiopsis* species.

Nocardiopsis strains isolated from saline or hypersaline soils or other habitats are easily identified using the criteria listed in Table 8.

Thermobifida

DIFFERENTIATION OF *THERMOBIFIDA* FROM OTHER GENERA Identification of *Thermobifida* strains at the generic level requires determination of several genus-specific markers, namely, the ability to grow at higher temperatures, formation of single spores on branched sporophores resulting in spore clusters on aerial mycelia and sometimes on non-fragmented substrate mycelia, cell wall chemotype III C, presence of cell wall teichoic acids, the highly saturated major menaquinones of the MK-10 series, phospholipid type P II, and fatty acid pattern type 3e (see Table 3).

Macroscopic and microscopic criteria as well as optimal growth temperature and medium are suitable for presumptive differentiation of *Thermobifida alba* and *Tb. fusca* from the other genera containing thermophilic species. Table 9 lists some thermophilic species of other genera with their conventional diagnostic markers. Chemotaxonomic markers support the separation of *Thermobifida* from the respective genera (Tables 3 and 4).

Menaquinones of *Thermobifida* with their highly saturated isoprenoid side chain are of diagnostic value. Up to five isoprene units may be saturated. In addition to the MK-10 series, minor amounts of menaquinones with 11 isoprene units, i.e., MK-11(H₄₋₁₀), are found. This pattern has been reported only for some mesophilic species of *Nocardiopsis* and *Micromonospora* (Fischer et al., 1983; Collins et al., 1984). Although the phospholipid type II is widely distributed among actinomycetes, it is useful for the differentiation of *Thermobifida* species from thermophilic species of the genera *Thermomonospora*, *Actinomadura*, *Microbispora*, *Nonomuraea*, *Saccharopolyspora*, or *Pseudonocardia* (Tables 4 and 8) or from mesophilic species of other genera which can grow at elevated temperatures, show similar morphological features, and/or synthesize hydrogenated major menaquinones of MK-10 or MK-11 series, e.g., *Nocardiopsis*, *Streptomonospora*, *Streptoalloteichus*, or *Catenuloplanes* (Table 4).

The analysis of fatty acids is quite useful to differentiate *Thermobifida* species from other actinomycete species with similar morphology or formerly referred to the genus *Thermomonospora* (Table 8). *Thermobifida* is characterized by

a high amount of *iso*- and *anteiso*-branched fatty acids, namely, 15-methyl-hexadecanoic acid (15–30%) and 14-methyl-hexadecanoic acid (15–30%), whereas *Thermomonospora* and *Actinomadura* species synthesize only traces of these fatty acids. In contrast, these latter taxa synthesize significant amounts of 10-methyl branched fatty acids, whereas this fatty acid is only a minor component in *Thermobifida* (1–5%). In *Thermobifida* species 2-hydroxy fatty acid (a diagnostic fatty acid in *Microbispora*) could not be detected. *Nocardiopsis* has a similar fatty acid type as *Thermobifida* (type 3e), but synthesizes significantly higher amounts of 10-methyl branched tuberculostearic acid (type 3d).

IDENTIFICATION OF *THERMOBIFIDA* SPECIES The two species of the genus *Thermobifida*, *Tb. alba* and *Tb. fusca*, can easily be differentiated from each other by the formation of spores on substrate mycelia, the ability to grow at different temperatures and pH ranges (Tables 9 and 10), resistance to specific inhibitors, and carbon utilization tests (McCarthy and Cross, 1984a). *Thermobifida alba* strains have the lower temperature optimum for growth and sporulation. McCarthy and Cross (1984a) reported that *Tb. alba* had an optimum of 40°C to 45°C as compared to 45°C to 50°C for *Tb. fusca* and that *Tb. alba* did not grow at 55°C on Czapek-Dox-yeast extract-casamino acid (CYC)-agar. Examination of temperature requirement of another set of strains on glucose-yeast extract-malt extract (GYM)-agar showed that *Tb. alba* strains grow best at 37–40°C whereas *Tb. fusca* strains prefer temperatures of 50 to 55°C. *Thermobifida fusca* prefers alkaline conditions for growth, while *Tb. alba* grows better at pH 7. In addition, the *Tb. fusca* strains were also reported to be more resistant to some growth inhibitors, e.g., crystal violet (0.00002%), sodium azide (0.01%), tetrazolium chloride (0.002%), and thalious acetate (0.001%; McCarthy and Cross, 1984a). Some strains of *Tb. alba* were shown to be unable to degrade elastin and keratin, in contrast to most other thermophilic monosporic actinomycetes, which are potent degraders of bio-polymers and usually demonstrate the almost identical degradation patterns (McCarthy and Cross, 1984a; Bös, 1994; Tables 10 and 11).

Strains of the two *Thermobifida* species show a different pattern of enzymes in cell free extracts, e.g., esterases and malate dehydrogenases in poly-acryl amide gel electrophoresis (Greiner-Mayi, 1988), which can be used to separate thermobifidas at the species level. In addition, the two *Thermobifida* species are well separated by quantitative differences in fatty acid pattern. *Thermobifida alba* synthesizes lower amounts of 15-methyl-hexadecanoic acid (13 to 17%) and higher amounts of tuberculostearic acid (5 to 8%), whereas 25–33% and

From McCarthy and Cross (1984a) and Kempf (1995).

1–2% of these acids, respectively, are found in *Tb. fusca*. However, these differences in fatty acid patterns might be a response to their different growth optima.

Since the value of phenotypic criteria for differentiation of the two current *Thermobifida* species is poor and the usefulness of 16S rDNA sequence similarity for identification of bacterial species at the molecular level is limited in some taxa, the new *Thermobifida* strains can be precisely attributed to *Tb. alba*, *Tb. fusca* or to new species only on the basis of polyphasic taxonomy, including examination of the DNA-DNA relatedness and other relevant studies (Vandamme et al., 1996; Stackebrandt et al., 2000; Rossello-Mora and Amann, 2001). New chemical compounds of cells and cell walls should also be evaluated for their taxonomic significance.

Streptomonospora salina

The genus *Streptomonospora* has a single species *S. salina* with only one isolate YIM 90002^T. It can be identified by unusual morphology, chemical markers, growth temperature, and salinity ranges (Table 3). This species produces white to pale yellow irregularly branched aerial mycelia where short chains of oval to rod-shaped spores (1.5–2 × 1 µm) with wrinkled surfaces are formed. The extensively branched substrate mycelium is non-fragmented. Single spores are oval to round (1.4–1.6 µm), borne on single or dichotomously branched sporophores developed on substrate hyphae. Spores of both types are non-motile. The cell wall of the type strain was reported to contain an unusual combination of amino acids (*meso*- and *DD*-diaminopimelic acids, glycine,

lysine and aspartate) but the structure of peptidoglycan has not been elucidated. Large amounts of glucose and galactose and smaller amounts of ribose, xylose, arabinose and mannose were present in whole cell hydrolysates. *Streptomonospora salina* is also characterized by the menaquinones MK-9(H₆) and with smaller amounts of MK-10(H₆) and MK-10(H₄) and by a phospholipid pattern of the P II type. Together with optima and ranges of temperatures and salinity for growth, *Streptomonospora salina* can be easily differentiated from *Thermobifida* and *Nocardiopsis*.

Menaquinone composition can be used to differentiate *Streptomonospora salina* from most other mesophilic spore-forming actinomycete genera containing hydrogenated menaquinones with relatively long isoprene side chains (Tables 3 and 4). A quite useful character for differentiation of *Streptomonospora salina* from most other spore-forming actinomycetes is its optimal growth at high salt concentration (15%). Besides *Streptomonospora salina*, only six halotolerant, moderately or extremely halophilic actinomycetes form long chains of spores and contain meso-diaminopimelic acid in the cell wall (Table 3). They belong to *Actinopolyspora* and *Nocardiopsis* (Gochner et al., 1975, 1989; Johnson et al., 1986; Yoshida et al., 1991; Yassin et al., 1993; Al-Tai and Ruan, 1994; Ruan et al., 1994; Ventosa et al., 1998; Chun et al., 2000). However, in contrast to *Streptomonospora salina*, these species have phospholipids of the P III type, their substrate hyphae are usually fragmented, and single spores (typical of *Streptomonospora*) are not formed on substrate hyphae. Compared with *Streptomonospora salina*, *Nocardiopsis* spp. produces much longer spore chains on aerial mycelia (aerial hyphae are almost fully disintegrated into spores), whereas actinopolysporas are characterized by IV cell wall chemotypes. Growth temperature, growth salinity range, and menaquinone composition may serve as additional characters for the differentiation of *Streptomonospora salina* from other taxa.

Current Taxonomic Position of *Nocardiopsis*, *Streptomonospora* and *Thermobifida*

After nearly 100 years of searching for a home for *Nocardiopsis dassonvillei* strains, the taxonomic position of this genus has now been elucidated. On the basis of chemotaxonomy, numerical taxonomy, DNA-DNA reassociation studies, and 16S rRNA gene sequence analyses (Fischer et al., 1983; Athalye et al., 1984, 1985; Kroppenstedt et al., 1985, 1990; Poschner et al., 1985; Stackebrandt, 1986; Goodfellow et al., 1988; Grund and Kroppenstedt, 1989, 1990;

Kroppenstedt et al., 1985, 1990; Meyer, 1989; Rainey et al., 1996; Stackebrandt et al., 1997; Zhang et al., 1998), many of the former *Nocardiopsis* species found their place within the genera *Lechevalieria* (Labeda et al., 2001), *Saccharothrix* (Grund and Kroppenstedt, 1989; Labeda and Lechevalier, 1989) and *Nonomuraea* (Zhang et al., 1998; Chiba et al., 1999). The current genus *Nocardiopsis* harbors twelve validly described species and one subspecies (Table 1).

The phylogenetic tree based on the comparison of the 16S rRNA gene sequences separates the *Nocardiopsis* species into four clusters (Fig. 4). The *N. dassonvillei* cluster includes the type species *N. dassonvillei* subsp. *dassonvillei* (strain DSM 43111) with its subspecies *N. dassonvillei* subsp. *albidorubidus* (DSM 40465), *N. dassonvillei* subsp. *dassonvillei* (DSM 43884) formerly *N. antarctica*, *N. synnemataformans*, and “*N. halotolerans*” (DSM 44410). The second cluster of low bootstrap replication values includes *N. alba*, *N. exhalans* (not shown), *N. prasina*, *N. listeri*, *N. tropica*, *N. lucentensis*, *N. umdischolae* (not shown) and *N. kunsanensis*, while *N. trehalosi* and *N. halophila* are distant single member clusters.

The comparison of the 16S rRNA gene sequences of *Nocardiopsis* with those of other actinomycetes revealed that the *Nocardiopsis* species show a homogeneous cluster apart from the other actinomycetes. On the basis of the isolated phylogenetic position and the unique morpho- and chemotaxonomic properties of this genus, Rainey and co-workers created the family Nocardiopsaceae (Rainey et al., 1996). Subsequently, the three families Nocardiopsaceae, Streptosporangiaceae and Thermomonosporaceae were unified into the suborder Streptosporangineae, one of the 10 suborders of the order Actinomycetales, class Actinobacteria (Stackebrandt et al., 1997).

Kroppenstedt and Goodfellow (1992) could show from the differences in chemical markers that the genus *Thermomonospora* was heterogeneous. They found that *Tm. alba* including *Tm. mesouviformis* and *Tm. fusca* merit generic status and should be removed from the genus *Thermomonospora* (Kroppenstedt and Goodfellow, 1992). Zhang and co-workers showed that the two *Thermomonospora* species, *T. alba* and *T. fusca*, differed significantly in their 16S rRNA gene sequences from *Thermomonospora sensu stricto* and form a separate branch closely affiliated with the *Nocardiopsis* line of descent. For these two misclassified *Thermomonospora* species, the second genus *Thermobifida* was created (Zhang et al., 1998).

The recently proposed third genus of the family, *Streptomonospora*, is represented by one species, *Streptomonospora salina*, which is posi-

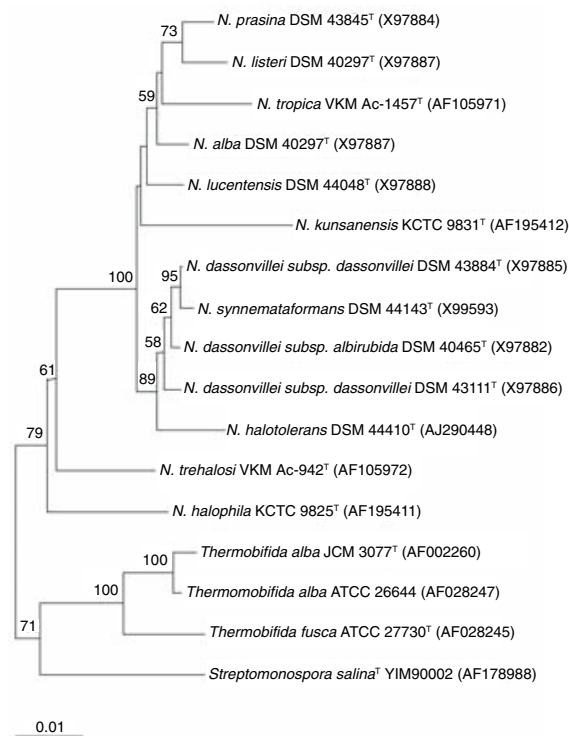

Fig. 4. Phylogenetic dendrogram obtained by distance matrix analysis showing the relationship among strains of the family *Nocardioseae*. The sequence of *Actinomadura* served as outside reference. Scale bar inferred nucleotide substitution per 100 nucleotides. The numbers at the nodes are bootstrap values.

tioned within the *Nocardioseae* phylogenetic clade and exhibits somewhat closer relatedness to thermobifidas than to most *Nocardioseae* species (Cui et al., 2001).

All three genera of family *Nocardioseae* (*Nocardioseae*, *Thermobifida*, and *Streptomonospora*) are clearly separated from each other and from all other actinomycetes by their unique combination of chemical markers, morphologies, physiological properties (Cui et al., 2001; Kroppenstedt, 1985, 1987; Kroppenstedt and Goodfellow, 1992; Zhang et al., 1998; Table 3), and molecular characteristics (Stackebrandt et al., 1983, 1997; Stackebrandt, 1986; Goodfellow et al., 1988; Kroppenstedt et al., 1990; Rainey et al., 1996; Zhang et al., 1998).

Recent publications and the 16S rRNA gene sequence data available from GenBank show that the family *Nocardioseae* harbors also many new organisms that are not yet validly described. Only those new actinomycete isolates should be included into the genera *Nocardioseae*, *Thermobifida*, and *Streptomonospora* that show the phenotypic properties

characteristic of these genera and/or are proven to be in these genera by 16S rRNA gene sequence analyses and other relevant taxonomic studies.

Preservation

For short-term preservation, sporulated strains may be kept on agar slants at 4°C and transferred every 4 months. To prevent the agar from drying, the tubes are tightly sealed with silicone stoppers. For longer preservation, spore suspensions or homogenized mycelia are mixed with glycerol to a final concentration of 25% and kept at 25°C (Wellington and Williams, 1978). Zippel and Neigenfind (1988) tested the viability, stability of auxotrophic markers, and antibiotic production of strains kept at 25°C in 45% glycerol. No drastic changes of the markers were noted after one year. Good results were obtained for non-sporulating strains by this method because the high concentration of glycerol prevents freezing of the suspension at 25°C. For long-term preservation, lyophilization of spores and mycelia suspended in 10% skim milk is a convenient method.

A very simple, reliable, and time-saving method is liquid nitrogen (N_2) cryopreservation of living cells in small polyvinyl chloride (PVC) tubes ("straws") at -196°C. This method has been described for long-term preservation of basidiomycetes (Hoffmann, 1989a, 1989b). The procedure has been tested for actinomycetes, including *Nocardioseae* and *Thermobifida*. The strains are harvested from well-sporulated cultures grown on suitable agar media in Petri dishes. A 2 × 25 mm piece of sterile PVC tube is pressed into the mycelial mat and the agar and carefully raised to excise the agar plug. This is repeated until the tube is filled with agar. The filled tubes are placed in a sterile cryo vial with the screw cap marked with strain accession number. A 1.8-ml vial will hold up to 13 tubes. Two vials are prepared for each strain and then fixed to a metal clamp for freezing in the gas phase of the liquid nitrogen container. After 10–15 min, when temperature falls below 130°C, the clamp can be positioned into the liquid phase at 196°C. A container with a capacity of 250 liters will hold at least 8,000 vials or 4,000 strains. For viability testing, one tube is removed from the vial within the gas atmosphere of the container and placed directly on a suitable agar medium for thawing. After a few days incubation, the mycelium will be visible. For those strains that do not produce an abundant mycelium, the plugs may be pushed out of the tubes by a sterile needle.

Physiology

The family harbors organisms with different temperature, salinity and alkalinity requirements for their growth and includes thermotolerant and thermophilic, halotolerant and moderately halophilic, as well as alkaliphilic or at least alkali-tolerant species. Their enzymes, antibiotics and other biologically active metabolites have applications in biotechnology and medicine. Although most members of the family are strict saprophytes, there is evidence that members of the genus *Nocardiopsis* are pathogens because they are found in clinical material, and airborne spores of *Thermobifida* species can be associated with the respiratory allergies.

Nocardiopsis

A high percentage of *Nocardiopsis* strains are usually found enriched under alkaline conditions in soil sources. Miyashita et al. (1984) reported that under these conditions, half of the actinomycetes strains belong to the genus *Nocardiopsis*. Table 6 shows that this taxon harbours many alkaliphilic or at least alkali-tolerant species. As expected, the alkaliphilic strains synthesize many different alkaline enzymes (Horikoshi and Akiba, 1982). Mikami et al. (1985) examined alkaliphilic amylase from these strains and found that the pH optimum was about 10. In contrast, the neutrophilic *N. dassonvillei* strains, which grow better at pH 7.5, synthesize amylase with a pH optimum of pH 8. Recently, Stamford et al. (2001) reported on a thermostable α -amylase from *Nocardiopsis* sp., an endophyte of yam bean. Thermostable amylolytic enzymes have been currently investigated to improve industrial processes of starch degradation.

An alkaline protease was isolated from *N. dassonvillei* strain ATCC 21944 by Kim et al. (1993). This protease showed maximum activity at pH 8.5. Only a small decrease in protease activity was found at pH 11, indicating that the protease of this strain is strongly alkaliphilic. The optimal temperature of the alkaline protease was 55°C; at 65°C however, it retains 70% of the enzymatic activity (Kim et al., 1993). The relatively strong thermal stability of the enzyme is of particular interest considering that the optimum growth temperature for most *Nocardiopsis* species is around 25°C and usually no growth occurs above 40°C (Table 7).

In a screening program searching for microbial metabolites with interesting properties, Mishra et al. (1987a) isolated 942 microorganisms from soil. Of these, 832 were aerobic actinomycetes. While the largest number (302) were streptomycetes, the other 530 isolates were distributed

among 17 different actinomycete genera, including 22 strains that were classified as *Nocardiopsis*. The *Nocardiopsis* strains had no effect on the tested algae or higher plants (Mishra et al., 1987a), but 6 of the 22 *nocardiopsis* isolates showed specific herbicidal properties. Four strains inhibited the germination of cress seeds and two affected barnyard grass seeds (Mishra et al., 1988). Bioassays for insecticidal properties from these strains were performed using mosquito larvae of *Aedes aegypti* and for nematocidal activities using the free-living nematode *Penagrellus revidivus*. One *Nocardiopsis* strain showed insecticidal properties, but none showed nematocidal properties (Mishra et al., 1987b). The growth of the fungus *Fusarium oxysporum* f. sp. *albedensis*, a pathogen of date palm, was inhibited by a *Nocardiopsis* strain (Sabaou and Bounaga, 1987). The growth of some other soil fungi was not affected by *Nocardiopsis dassonvillei* extracts. Papeta and co-workers isolated from *Nocardiopsis* strain A6 a factor inhibiting the growth of some phytopathogenic fungi. This proteinaceous toxin was identified as a xylanase that showed 100% sequence homology with the xylanase from *Bacillus circulans* (Papeta et al., 1995).

Phenazine antibiotics were extracted from the mycelium of the alkaliphilic *Nocardiopsis* strain OPC-15 (Tsujibo et al., 1988). This strain produced different phenazine antibiotics under different culture conditions (incubation period, incubation temperature, and temperature shift). In addition, 1,6-dihydroxyphenazine (compound III) was obtained from the mycelium after incubation for 6–8 days at 27°C, while 1,6-dihydroxyphenazine 5,10 dioxide, known as iodinin (compound I), was isolated after incubation for 6 days at 27°C followed by further incubation for 2 days at 4°C. A new disaccharide antibiotic (3-trehalosamine) active against Gram-positive bacteria was reported to be synthesized by *Nocardiopsis trehalosi* (Dolak et al., 1980; Dolak et al., 1981). Members of the genus can produce an apoptolidin, a new apoptosis inducer in transformed cells (Kim et al., 1997).

The production of a new indole alkaloid, pendolmycin, by *Nocardiopsis* strain SA 1715, isolated from soil collected in a river near Shanghai, was reported (Yamashita et al., 1988). Pendolmycin is an inhibitor of phosphatidyl inositol turnover induced in human epidermoid carcinoma by epidermal growth factor. The structurally related metabolites, teleocidin B and lyngbyatoxin, have been isolated from a *Streptomyces* strain and from lipid extracts of a Hawaiian shallow-water variety of the *Lyngbya majuscula*, respectively. The production of pendolmycin (structurally similar to teleocidin A; Nishiaki et al., 1991) and methylpendolmycin

(Sun et al., 1991) was attributed to other *Nocardio-opsis* strains. A cytotoxic substance TS-1 was isolated from the alkaliophilic *Nocardio-opsis* strain OPC-553 regarded as a strain of *Nocardio-opsis dassonvillei* subsp. *prasina* (Tsujibo et al., 1990c). It showed a marked inhibitory activity against L5178Y mouse leukemic cells in vitro. TS-1 was identified as the antifungal antibiotic, kalafungin, already isolated from the culture broth of *Streptomyces tanashiensis*. Thus, the same secondary metabolite may be synthesized in different taxa, indicating that the occurrence of a metabolite may not always have taxonomic relevance.

The antinflammatory and antiallergic effects of kinase C inhibitors are well known. Protein kinase C inhibitors of microbial origin are intensively studied because of their physiological and medical importance (Koizumi et al., 1988; Matsuda and Fukuda, 1988; Nakanishi et al., 1988; Ohmori et al., 1988; Iwabe et al., 1998; Kim and Kawai, 1998; Arvanov et al., 2000; Bishop et al., 2000; Takahashi et al., 2000). New protein kinase C inhibitor designated "K-252a" was found to be produced by an unclassified *Nocardio-opsis* strain K-252 (Kase et al., 1986; Matsuda and Fukuda, 1988). Three structurally related compounds, K-252b, c, and d, were isolated from a culture broth of a *Nocardio-opsis* isolate K-290 (Nakanishi et al., 1986).

"*Nocardio-opsis atra*" IFO 14198, a producer of nocardicin A, was described by Celmer et al. (1980). It should be mentioned that the latter two strains cited in this section as *Nocardio-opsis* may have been misclassified because they were assigned to this genus solely on the basis of morphology and limited chemical markers such as cell wall composition. Subsequently, strain K-252 (= NRRL 15532) was reclassified as a new species of the genus *Nonomuraea*, *Nonomuraea longicatena* (Chiba et al., 1999). The other strain, "*Nocardio-opsis atra*," possesses phospholipids of the P II type (Streshinskaya et al., 1989) and belongs to the Pseudonocardiaceae (L. I. Evtushenko, unpublished observation).

Members of the genus *Nocardio-opsis* degrade biopolymers very actively (Kempf and Kutzner, 1988; Tsujibo et al., 1990a, 1990b, 1990c, 1990d, 1991; Kempf, 1995). Table 11 gives examples of the degradation capabilities of some selected *Nocardio-opsis* strains. All of the 12 strains were able to degrade gelatin, casein, elastin, Tween 80, blood and *Micrococcus luteus* cells. Particularly total hemolysis is of special interest because this ability is not common among other sporoactinomycetes. Differences could be found in the degradation capabilities of the *Nocardio-opsis* species in the degradation of starch, xylan, lecithin, and polyhydroxybutyrate (PHB). Starch was only slowly degraded by the mesophilic species,

whereas the thermotolerant and thermophilic strains had a very active amylase. Xylanase was only produced by *N. dassonvillei* strains, although a little xylanase activity could be detected in *N. listeri*. The data of Kempf (1995) support the results of Tsujibo et al. (1990d), (1991), who detected three xylanases in isolate OPC-18 assigned to *Nocardio-opsis dassonvillei* subsp. *alba*. Protease activity was present in *N. prasina*. This confirms the results of Tsujibo et al. (1990a), (1990b), who found two serine proteases in this species. In contrast to the other *Nocardio-opsis* species, *N. dassonvillei* was lecithinase negative. Two *N. dassonvillei* strains, two *N. alba* strains, and the thermotolerant *Nocardio-opsis* strain DSM 40936 degraded PHB. There is also a report showing *Nocardio-opsis* strain NCIMB 5124 from oil-contaminated marine environments can degrade hydrocarbons (crude oil) and utilize organic nitrogen by producing extracellular proteases (Dixit and Pant, 2000a; Dixit and Pant, 2000b). Both enzymes were identified as alkaline serine endopeptidases.

A screening program for metal leaching microorganisms from a siliceous alkaline slag dump led to the isolation of an actinomycete (Willscher and Bosecker, 2001). A polyphasic taxonomic study showed that this isolate belongs to a new *Nocardio-opsis* species for which the tentative name "*Nocardio-opsis metallicus*" was chosen, referring to its ability to separate metal from slag (Schippers et al., 2002).

Thermobifida

Biological and physiological features of *Thermobifida* reflect their adaptive potential to their natural habitat, which is mainly self-heated organic material. Thermobifidas share this habitat with other thermophilic and thermotolerant actinomycetes able to degrade plant material and other bio-polymers (McCarthy, 1987; Tables 10 and 11). From this environment *Tb. fusca* strains have been isolated that are able to mineralize plastic disposals and other anthropogenic xenobiotica (Kleeberg et al., 1998). Actinomycetes are well suited for this environment because they generally grow as branching hyphae and are well adapted to penetration and degradation of insoluble substrates such as lignocellulose. Within this taxon, thermobifidas are of particular interest because they produce multiple thermostable enzymes involved in the degradation of lignocellulose (McCarthy, 1987; Wong et al., 1988; Ball and McCarthy, 1989). Knowledge of lignocellulolytic activity is important to the understanding of plant biomass recycling in nature and the use of enzymes in controlled lignocellulose conversation (Thomson, 1993). *Thermobifida* strains are also capable of producing ferments degrading

other biopolymers. These enzymes were able to degrade all of the 16 tested polymers and substrates except chitin (Tables 9 and 11). A novel non-heme extracellular peroxidase was isolated from the thermophilic strain *Thermobifida* (*Thermomonospora*) *fusca* BD25 and its catalytic mechanism was characterized (Rob et al., 1995; Rob et al., 1996; Rob et al., 1997b; Rob et al., 1997a). Optimization of fermentation product yields under aerobic bioreactor conditions was reported (Tuncer et al., 1999).

Thermobifida and other thermophilic monosporic actinomycetes have been evaluated for cellulose bioconversion processes designed to produce single-cell protein (Bellamy, 1974, 1977; Wood, 1985; Crawford, 1988) or sugar syrups for fermentation to ethanol (Hägerdal et al., 1979; Lee and Humphrey, 1979; Ball and McCarthy, 1988). Several of these publications have referred to a cellulolytic *Thermoactinomyces* strain that has been labeled "*T. cellulosa*" (Vacca and Bellamy, 1976). This organism was later transferred to *Thermomonospora fusca* (Hägerdal et al., 1980), which was recently reclassified together with *Thermomonospora alba* to the new genus *Thermobifida* (Zhang et al., 1998).

Thermobifida fusca shows endoglucanase activity and attacks cellulose. It is assumed that *Tb. fusca* is involved in the formation of humic substances in soil (Trigo and Ball, 1994). *Thermobifida* strains are capable of extensively degrading cellulose and lignocellulose residues that make up the bulk of agricultural and urban wastes (McCarthy, 1987). *Thermobifida fusca* strains are very active against arabinoxylan and produce thermostable enzymes (McCarthy et al., 1985).

Thermobifida fusca was grown at 55°C on a pilot scale to convert high cellulose, low lignin pulp mill waste into single-cell protein (Crawford et al., 1973). The proteinaceous product had a high nutritional value as a feed supplement in the diet of chicks (Harkin et al., 1974). Thermostable cellulases are also attractive as catalysts in biomass conversion, since their temperature optima can reduce contamination problems in economically feasible non-aseptic applications (Wood, 1985; Bachmann and McCarthy, 1991). A cellulase-enhanced *Thermobifida fusca* mutant grown on chemically pretreated poplar wood was found to use 70% of the woody biomass after 62 h at 55°C, but failed to grow well on wood that had not been chemically pretreated. Bellamy (1977) used the parental strain of the same organism, originally described as "*Thermoactinomyces cellulosa*," for the bioconversion of chemically pretreated lignocellulosic feedlot waste into microbial biomass. The culture degraded up to 85% of the cellulosic and over 90% of the hemicellulosic fraction of the sub-

strate. The process led to the production of a high protein content product but was not economical, given the cost of the chemical pretreatment needed to obtain a suitable degradable substrate.

Some success has been achieved in the use of thermophilic actinomycetes in processes designed for the saccharification of purified celluloses. The cellulase complex of *Tb. fusca* YX readily saccharifies finely ground, acid swollen Avicel, a purified chemically pretreated cellulose (Su and Paulavicius, 1975; Ferchak and Pye, 1980). In subsequent work by Ferchak and Pye (1983), a process was developed for saccharification of cellulose using a cellulose/cellobiose mixture. In a 7-day, 50°C saccharification, 15 to 20% glucose syrups were generated from acid swollen Avicel. The availability of cellulase-overproducing strains of *Thermomonospora* and *Thermobifida* species (Fennington et al., 1982; Meyer and Humphrey, 1982) should further improve the commercial potential of saccharification processes. *Thermobifida fusca* was also reported to secrete thermostable β -mannanase (at a temperature optimum of 80°C), which hydrolyzes the O-glycosidic bonds in mannan, a hemicellulose constituent of plants, and has potential use in pulp and paper production. The three-dimensional structure of a mannan-degrading enzyme was reported for the first time and a possible mechanism of enzyme selectivity was described (Hilge et al., 1998; Hilge et al., 2001).

Ligninolytic thermomonosporas may have potential for the biological bleaching of pulps or in biological pulping processes, given their capacity to dissolve lignin and separate it from the cellulose component of lignocellulose (McCarthy et al., 1986). It has also been suggested (Crawford, 1988) that the ability of some *Thermobifida* (*Thermomonospora*) strains to simultaneously attack all of the major components of lignocellulose, (i.e., cellulose, lignin and hemicellulose) may be used to develop direct fermentations for the conversion of lignocellulosic wastes into specific high value chemicals and for single cell protein. The development of efficient industrial size bioreactors for solid substrate fermentations will help to foster commercially successful actinomycete-adapted bioconversion processes. The biochemistry and genetics involved in these processes have been intensively studied for *Tb. fusca* during the last years (Irwin et al., 1998; Irwin et al., 2000; Spiridonov and Wilson, 1998; Spiridonov and Wilson, 1999; Spiridonov and Wilson, 2001; Tuncer et al., 1999; Zhang et al., 2000a; 2000b).

During a screening program for micro organisms degrading plastic waste disposals like BTA (random aliphatic-aromatic copolyesters synthesized from 1,4-butanediol, adipic, and tereph-

thalic acid), 20 BTA-degrading strains were isolated from the mature compost of green waste. Among these micro organisms, thermophilic actinomycetes obviously play an outstanding role and appear to dominate the initial degradation step of BTA. Two of the isolates, which exhibited about a 20-fold higher BTA degradation rate than usually observed in common compost tests, were identified as members of the species *Thermobifida fusca*. Further studies on strains received from culture collections showed that all tested *Thb. fusca* strains show the ability to degrade BTA (Kleeberg et al., 1998).

Members of the genus *Thermobifida* were also reported to be producers of substances of medical importance. A novel inhibitor of topoisomerases designated "topostatin" was isolated from the culture filtrate of *Thermomonospora alba* strain no. 1520 (Suzuki et al., 1998a). Topostatin inhibited the relaxation of supercoiled pBR322 DNA by calf thymus topoisomerase I and also inhibited the relaxation of supercoiled pBR322 DNA and decatenation of kinetoplast DNA by human placenta topoisomerase II. The inhibitor exhibited growth inhibition activity against tumour cells (SNB-75 and SNB-78) of the central nervous system, but did not exhibit any antimicrobial activity against Gram-positive and Gram-negative bacteria, yeasts and fungi (Suzuki et al., 1998a; Suzuki et al., 1998b). The inhibitor of topoisomerase I designated "isoaurostatin" was isolated, and its features and structure were studied. It was determined to be 6,4'-dihydroxyisaurone, an inhibitor of the cleavable complex-nonforming type without DNA intercalation (Suzuki et al., 2001).

Pathogenicity for Humans

Nocardiosis

Although *Nocardiosis* strains were frequently isolated from patients (Liegard and Landrieu, 1911), doubt of their clinical significance was expressed for a long time. Sindhuphak and co-workers showed that actinomycetoma was caused by *Nocardiosis dassonvillei* and repeatedly isolated *N. dassonvillei* strains from nodules and draining sinuses of the anterior aspect of the right leg below the knee of a 39-year-old man (Sindhuphak et al., 1985). This was the first reported case of mycetoma caused by *N. dassonvillei*. Recently a *Nocardiosis dassonvillei* strain has been isolated from the blood of a patient suffering from cholangitis. The isolate was recovered from blood when the patient presented an acute onset of fever. The biliary and gastrointestinal tracts may be the entry routes, since *N.*

dassonvillei was recovered after retrograde cholangiography. Alternatively, an intravenous catheter inserted while the patient was hospitalized may have been the entry route. Since *N. dassonvillei* was isolated on the 10th day of hospitalization, it should be regarded as a potential nosocomial pathogen (Beau et al., 1999). Another *Nocardiosis* species of clinical significance is *Nocardiosis synnemataformans*. It was isolated from the sputum of a kidney transplant patient, but in this case, the pathogenicity of the isolate could not be verified (Yassin et al., 1997). The role of *Nocardiosis dassonvillei* in broncho pulmonary disorders was clearly demonstrated by Gugni et al. (1998). In a study of aerobic actinomycetes in human infections in Nigeria, they found two patients with *Nocardiosis dassonvillei* among 42 patients with broncho pulmonary disorders. The patients were asthmatics and had long histories of corticosteroid therapy. In the same year, Mordarska et al. (1998) identified *N. dassonvillei* (by glycolipid markers) as the only etiological agent of a severe pulmonary infection. The identification by this marker was confirmed by DNA/DNA homology studies. These results demonstrated the value and generic specificity of glycolipid markers from *Nocardiosis*. This was the first time that the immunologically active glycolipid markers G(1) and G(2) were used for rapid recognition of a clinical strain causing a nocardiosis.

Corynebacterium—Nonmedical

WOLFGANG LIEBL

Introduction

Corynebacterium is a genus within the actinomycetes subphylum of Gram-positive eubacteria (Stackebrandt et al., 1997). These rod-shaped bacteria have DNA with a high G+C content and irregular (“coryneform”) cell morphology. The phylogeny and taxonomy of corynebacteria (see Phylogeny and Taxonomy) have been changed many times, but modern methods of chemotaxonomy and molecular systematics now provide adequate means for the reliable identification and classification of *Corynebacterium* species.

Currently, there are more than 50 validated species of *Corynebacterium*. A large number of these (30) was described in the last ten years. Most *Corynebacterium* species are considered to be of medical significance and are therefore treated in chapter *Corynebacterium*—Medical in the second edition, whereas the following will be treated:

- C. ammoniagenes* (other name: *Brevibacterium ammoniagenes* [basonym]; Cooke and Keith, 1927; Collins, 1987b)
- C. amycolatum* (Collins et al., 1988)
- C. callunae* (Lee and Good, 1963; Yamada and Komagata, 1972a; Yamada and Komagata, 1972b)
- C. casei* (Brennan et al., 2001)
- C. flavesceus* (Barksdale et al., 1979)
- C. glutamicum* (other names: *Brevibacterium divaricatum* [subjective synonym], *Corynebacterium lilium* [subjective synonym]; Kinoshita et al., 1958; Abe et al., 1967; see Liebl et al., 1991)
- C. mooreparkense* (Brennan et al., 2001)
- C. terpenotabidum* (formerly *Arthrobacter* spec.; Ikeguchi et al., 1988; Takeuchi et al., 1999)
- C. variabile* (formerly *C. variabilis*, nom. corrig. Int. J. Syst. Bacteriol. 48:1073; other names: *Arthrobacter variabilis* [basonym], *Caseobacter polymorphus* [subjective synonym]; Müller, 1961; Collins, 1987a; Collins, 1989b)
- C. vitaeuruminis* (formerly *C. vitarumen*, nom. corrig. Int. J. Syst. Bacteriol. 47:908; other name: *Brevibacterium vitarumen* (basonym); Bechdel et al., 1928; Lanéelle et al., 1980)

In addition to the species listed above, certain bacteria frequently encountered in the relevant literature will be discussed, i.e., “*C. lilium*,” “*Brevibacterium flavum*,” “*Brevibacterium lactofermentum*” and *Brevibacterium divaricatum*. None of these nomenclatural “*Brevibacterium*” species is a true member of the genus *Brevibacterium*. Numerous data exist (Abe et al., 1967; Minnikin et al., 1978; Suzuki et al., 1981; W. Liebl et al., unpublished data) indicating their close relatedness if not identity with *C. glutamicum*. Indeed, the type strains of *B. divaricatum* and *C. lilium* and some representative strains of “*B. flavum*” and “*B. lactofermentum*” were transferred to *Corynebacterium glutamicum* (Liebl et al., 1991).

These organisms treated in this chapter were originally isolated from very diverse habitats. Some of them are industrially important bacteria used in large-scale biotechnological applications. The characteristic features of the genus *Corynebacterium* as outlined by Collins and Cummins (1986b) are also true for the bacteria of this section: Gram-positive (sometimes unevenly stained), nonsporeforming, nonmotile, not acid-fast, straight or slightly curved rods, ovals or clubs, often with metachromatic granules, often typically V-shaped arrangement of cells (see Fig. 1), facultatively anaerobic to aerobic, catalase positive, chemo-organotrophic, peptidoglycan directly crosslinked of the type A1 γ (Schleifer and Kandler, 1972) with meso-diaminopimelic acid (meso-A₂pm) as the cross-linking amino acid, predominant cell wall sugars are arabinose and galactose, mycolic acids (corynemycolic acids = short-chain α -substituted- β -hydroxy acids with 22–36 carbon atoms) present except in *C. amycolatum*, straight-chain saturated or monounsaturated fatty acids, 10-methyl-branched chain acids may be present, and eight and/or nine isoprene unit dihydrogenated menaquinones. It is important to note that members of *Corynebacterium* and related bacteria have an unusual cell envelope structure when compared to other Gram-positive bacteria. Including the reclassified and new species of *Corynebacterium*, the genus has a DNA base composition covering a wide range of approxi-

Fig. 1. Phase contrast microphotograph of *Corynebacterium glutamicum* cells grown in BMCG synthetic broth for 16 h. Bar = 10 μ m.

mately 46–71 mol% G+C, but most species have between 51 and 68 mol% G+C.

Phylogeny and Taxonomy

Corynebacteria belong to the large group of Gram-positive bacteria with a high G+C content of their DNA (generally above 50 mol%, with a few exceptions) and represent one of the main lines of descent within the domain Bacteria. This group was described on the basis of 16S-rRNA cataloguing as part of the actinomycetes subdivision or subphylum of Gram-positive eubacteria (Stackebrandt and Woese, 1981). Chemotaxonomic studies comparing the cell wall composition (peptidoglycan structure and occurrence of mycolic acids) and lipid profiles suggested that the genera *Mycobacterium*, *Nocardia* and *Rhodococcus* are close relatives of *Corynebacterium* and led to the proposal to combine the four into the so-called “CMN-group” (Barksdale, 1970). Later, it was suggested to place these genera together with *Caseobacter* (later transferred to *Corynebacterium*; Collins et al., 1989b) into a group called “*Mycobacteriaceae*” (Barksdale, 1981; Jones and Collins, 1986). A different classification concept considered the genera *Corynebacterium* and *Mycobacterium* separately and combined the other mycolate-containing, cell wall type IV actinomycetes into the family *Nocardiaceae* (see Goodfellow, 1992). In principle, the grouping of taxa based on the chemotaxonomic markers just mentioned (chemotype IV and mycolic acids) proved to be correct. This classification concept withstood rigorous phylogenetic analysis, i.e., 16S rDNA sequence comparison, and now it is clear that the CMN-group, which from today’s standpoint encompasses the genera *Corynebacterium*, *Dietzia*, *Gordona*, *Mycobacterium*, *Nocardia*, *Rhodococcus*, *Tsuka-*

murella and the mycolateless *Turicella*, forms a robust monophyletic taxon (Pascual et al., 1995; Ruimy et al., 1995).

In 1997, a new hierarchical classification system was proposed for the actinomycete subphylum (Stackebrandt et al., 1997). In this comprehensive system, the delineation of taxa is based solely on 16S rRNA/rDNA sequence data. The organisms and the families they belong to are placed into a phylogenetically meaningful framework of higher taxa under the umbrella of the new class *Actinobacteria*. In this classification concept, the genera *Corynebacterium* and *Turicella* form the family *Corynebacteriaceae*, one of six families (*Corynebacteriaceae*, *Dietziaceae*, *Gordoniaceae*, *Mycobacteriaceae*, *Nocardiaceae* and *Tsukamurellaceae*) within the suborder *Corynebacterinae* within the order *Actinomycetales* within the subclass *Actinobacteridae* within the class *Actinobacteria*. A pattern of 16S rDNA signatures characteristic for the family *Corynebacteriaceae* was described by Stackebrandt et al. (1997).

In the course of the decades after creation of the genus *Corynebacterium* by Lehmann and Neumann (1896), many bacterial isolates were assigned to the genus, often for reasons not justifiable from a modern taxonomic point of view. Therefore, the genus *Corynebacterium* traditionally comprised an extremely diverse collection of microorganisms, accommodated in one group mainly on the basis of their common cell morphology, staining properties and respiratory metabolism. Obviously, the sole use of these criteria could not result in a homogenous group of organisms. Chemotaxonomic markers later helped to redraw the borderline of the genus *Corynebacterium*, and subsequently the transfer of various species from *Corynebacterium* to other genera, as well as the inclusion of species previously placed elsewhere, was published (Collins and Bradbury, 1986a; Collins and Cummins, 1986b; Collins, 1987a; Collins, 1987b; Collins et al., 1988; Collins et al., 1989a). More recently, a number of new species of *Corynebacterium* were described, i.e., 30 new species were validly published between 1991 and 2001. Most of them were isolated from clinical and veterinary specimens. This fact indicates that the genus presumably contains many opportunistic pathogens. None of the plant pathogenic coryneform bacteria listed in the eighth edition of *Bergey’s Manual of Determinative Bacteriology* (Cummins et al., 1974), which were treated as members of the genus *Corynebacterium* for many years, is a true *Corynebacterium sensu stricto* (see Collins and Bradbury, 1986a). This notion was supported mainly by the accumulation of chemotaxonomic data (i.e., cell wall composition, mycolic acid content and mol% G+C) argu-

ing against the retention of phytopathogenic “corynebacteria” in the genus and finally led to the reclassification of these bacteria in other genera, mainly in *Curvobacterium* and *Clavibacter* (Collins and Jones, 1982a; Collins and Jones, 1983; Collins et al., 1981; Collins et al., 1982c; Goodfellow, 1984b; Goodfellow, 1984a; Davis et al., 1984). These genera are now classified in a different suborder (*Micrococcinae*) of the order *Actinomycetales* than *Corynebacterium* (suborder *Corynebacterinae*; see Stackebrandt et al., 1997).

Comparative 16S rDNA sequence analysis of the *Actinomycetales* taxa with cell wall chemotype IV and mycolic acids revealed that these taxa, including *Corynebacterium*, *Dietzia*, *Gordonia*, *Mycobacterium*, *Nocardia*, *Rhodococcus*, and *Tsukamurella*, and the mycolate-less *Turicella* form a natural suprageneric group (Pascual et al., 1995; Ruimy et al., 1995). Within this group, the species of the genus *Corynebacterium* apparently form a monophyletic association, although the genus exhibits considerable phylogenetic depth. Interestingly, the mycolic acid-less species *C. amycolatum* and the single species of *Turicella*, *T. otitidis* (Funke et al., 1994), which also lacks mycolic acids, were found to form deep branches close to the periphery of the genus *Corynebacterium* (Pascual et al., 1995). However, this phylogenetic position of *Turicella* was not confirmed by Ruimy et al. (1995), who reported that the genus appeared as a branch included within the *Corynebacterium* unit and suggested the standing of *Turicella* as a separate genus be re-evaluated.

Despite the improvements in the phylogenetic affiliation and taxonomy of *Corynebacterium* species, it should be kept in mind that the genus is phenotypically still very diverse and contains both aerobes and facultative anaerobes, both mycolate- and non-mycolate-containing species, both tuberculostearic acid- and non-tuberculostearic acid-containing species, and both medically important species and saprophytic, nonpathogenic species. Today, more than 50 validated species of *Corynebacterium* are known, many of which (30) were described in the last ten years. A 16S rDNA sequence-based phylogenetic tree of the species belonging to the genus is shown in Fig. 2.

In the literature, the term “coryneform bacteria” (the origin of this expression and its introduction into the literature was examined by Keddie, 1978) was previously sometimes used as a supergeneric group designation. From today's point of view, this practice is troublesome because the term traditionally was applied to a diverse collection of bacteria of various genera (e.g., *Arthrobacter*, *Brevibacterium*, *Cellulomonas*, *Corynebacterium*, and

Fig. 2. Unrooted tree of the phylogenetic relationships among the species of the genus *Corynebacterium*. The tree, which is based on 16S rDNA sequence data and was constructed by the neighbour-joining method, was kindly supplied by Dr. T. M. Cogan, Dairy Products Research Centre, Fermoy, County Cork, Ireland. Bootstrap values, expressed as percentages of 1000 replications, are given at the branch points.

Mycobacterium, to name just a few; see Keddie, 1978 and Goodfellow and Minnikin, 1981). The rather confusing situation is best documented by the concept of the chapter entitled “Coryneform Group of Bacteria” in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Rogosa et al., 1974), where, as Barksdale (1981) points out, *Corynebacterium* is placed “along with a polytypic array of bacteria whose common property would seem to be pleomorphism.” The advanced classification methods available now have led to a sophisticated picture of the interrelationships between the genera comprising the coryneform organisms (see Stackebrandt et al., 1997). The term “coryneform” is taxonomically not satisfactory and should be avoided where possible. It may nevertheless be a useful expression if used as a purely descriptive term of bacterial morphology.

Habitat

The bacteria discussed in this chapter were originally isolated from a broad variety of habitats, including soil, feces, dairy products, animal skin, and plant material (Liebl, 1992a; Table 1). *Arthrobacter variabilis* and *Caseobacter polymorphus*, both now accommodated in the new species *Corynebacterium variabile* (Collins, 1987a; Collins et al., 1989b), were originally isolated from animal fodder and cheese, respectively (Müller, 1961; Crombach, 1978). In a numerical taxonomic study of cheese-smear coryneform bacteria isolated from the rind of different cheese varieties, Seiler (1986) found that about 20% of the white and yellow coryneform isolates clustered in a phenon closely resembling the "*Brevibacterium ammoniagenes*" group of Seiler (1983a). Recent work dealing with the microflora of smear-ripened cheeses resulted in the description of two new species of *Corynebacterium*, i.e., *C. mooreparkense* and *C. casei* (Brennan et al., 2001). Other cheese-smear isolates were classified as *C. ammoniagenes* and *C. variabile* (Eliskases-Lechner and Ginzinger, 1995; Valdes-Stauber et al., 1997). Strains classified as "*Brevibacterium ammoniagenes*" (*C. ammoniagenes*) and *C. glutamicum* with numerical taxonomy methods were isolated from piggery wastes by Seiler and Hennlich (1983b). Interestingly, significant numbers of bacteria displaying properties characteristic of the genus *Corynebacterium* have been isolated from marine samples (Bousfield, 1978). However, these isolates were not differentiated to the species level and they were not investigated with molecular systematics methods. Nevertheless, it seems that nonmedical corynebacteria are widely disseminated in nature, although there are no data available concerning the numbers present in different habitats.

Isolation

Nonmedical corynebacteria can be isolated from a variety of different habitats (Liebl, 1992a; see above and Table 1). However, to the authors' knowledge, no selective media or enrichment procedures have been described which are specifically devised for this group of organisms.

Most strains normally grow well if cultivated aerobically at 30°C in standard peptone-yeast extract media like the *Corynebacterium* medium (DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH, 1998 catalogue of strains, medium no. 53) shown below, although growth on very rich media such as brain heart infusion (Difco) is generally faster and more abundant.

Corynebacterium Medium

Casein peptone, tryptic digest	10 g
Yeast extract	5 g
Glucose	5 g
NaCl	5 g
(Agar)	15 g)
Distilled water	1,000 ml
pH 7.2–7.4	

For *C. ammoniagenes*, a chemically defined medium was described by Nara et al. (1969a). For *C. glutamicum*, synthetic media, e.g., BMCG-broth (Liebl et al., 1989b; see recipe below), have been designed which support abundant growth of this species. The addition of certain substances such as 0.1% citrate or low concentrations (10^{-5} M) of some dihydroxyphenolic compounds (catechol and protocatechuate) has been shown to greatly stimulate growth of *C. glutamicum* in synthetic broth, presumably by assisting in the assimilation of iron by this organism (Von der Osten et al., 1989; Liebl et al., 1989b).

BMCG Synthetic Broth:

(NH ₄) ₂ SO ₄	7 g
Distilled water	850 ml
10 × M9 solution	100 ml

Autoclave 20 min., 121°C, then add aseptically:

200 × Salt solution	5 ml
Trace element solution	2 ml
1 M CaCl ₂	0.05 ml
Vitamin stock solution	1 ml
20% Glucose	50 ml
10 mM Catechol	1 ml

(To prepare 10 × M9 stock, add 60 g of Na₂HPO₄, 30 g of KH₂PO₄, 5 g of NaCl, and 10 g of NH₄Cl to 1,000 ml of distilled H₂O, and adjust to pH 7.3; to prepare 200 × salt solution, add 80 g of MgSO₄ · 7H₂O, 4 g of FeSO₄ · 7H₂O, 0.4 g of MnSO₄ · H₂O, and 5 g of NaCl to 1,000 ml of distilled H₂O; to prepare trace element solution, add 88 mg of Na₂B₄O₇ · 10H₂O, 40 mg of (NH₄)₆Mo₇O₂₄ · 4H₂O, 10 mg of ZnSO₄ · 7H₂O, 270 mg of CuSO₄ · 5H₂O, 7.2 mg of MnCl₂ · 4H₂O, and 870 mg of FeCl₃ · 6H₂O to 1,000 ml of distilled H₂O; to prepare vitamin stock solution, add 1 mg of biotin and 10 mg of thiamine HCl per 1 ml of distilled H₂O; the 200 × salt solution, trace element solution and 1 M CaCl₂ are autoclaved separately, and the vitamin and glucose solutions are filter sterilized; the catechol stock is adjusted to a neutral pH, sterilized by filtration, stored in aliquots at –20°C and added aseptically to the medium just before inoculation.)

Corynebacteria are generally exacting in their nutritional requirements. It is noteworthy that all strains of glutamic acid-producing corynebacteria (*C. glutamicum* and similar bacteria) are dependent upon the presence of biotin in the growth medium, and some additionally require

thiamine or *p*-aminobenzoic acid (Abe et al., 1967).

Identification

MORPHOLOGY For *C. glutamicum* cells grown in various media and sampled after different incubation periods, we have not encountered problems in recognizing the morphological features typical of *Corynebacterium*, i.e., somewhat irregular rod-shaped cells, often arranged in V-formations, and so forth. However, morphological differences occur depending on the media used and the culture age (Fig. 1). Therefore, for the investigation of the species described in this chapter and to have reproducible culture conditions for reasons of comparison, it may be useful to employ EYGA medium when examining morphological features as recommended by Cure and Keddie (1973).

EYGA Medium:

K ₂ HPO ₄	1.1 g
KH ₂ PO ₄	0.86 g
CaCl ₂	0.025 g
MgSO ₄ · 7H ₂ O	0.2 g
NaCl	0.1 g
(NH ₄) ₂ SO ₄	0.5 g
Yeast extract	1 g
Glucose	1 g
Vitamin B ₁₂	0.002 mg
Trace element solution	3 ml
Agar	12 g
Distilled water	1,000 ml
Adjust to pH 6.8	

(To prepare trace element solution, add 5 g of EDTA, 2.2 g of ZnSO₄ · 7H₂O, 0.57 g of MnSO₄ · 4H₂O, 0.5 g of FeSO₄ · 7H₂O, 0.161 g of CoCl₂ · 6H₂O, 0.157 g of CuSO₄ · 5H₂O, and 0.151 g of Na₂MoO₄ · 2H₂O to 600 ml of distilled water.)

IDENTIFICATION OF CORYNEBACTERIUM SENSU STRICTO AND DIFFERENTIATION FROM OTHER GENERA A bacterial isolate which fulfills the following criteria can be considered to be a member of the *Corynebacterium* sensu stricto: facultatively anaerobic or aerobic, coryneform morphology, cell wall containing meso-A₂pm, arabinose and galactose and short-chain mycolic acids with 22–36 carbon atoms, and 51–65 mol% G+C. Using these criteria only, certain rhodococci may be confused with *Corynebacterium*, although their mol% G+C (approximate range for *Rhodococcus* is 60–69%) is generally higher than that found for most corynebacteria. Also, rhodococci are considered to be aerobes, whereas most representatives of *Corynebacterium* are facultatively anaerobic.

Mycolic acids (2-alkyl-branched-3-hydroxyacids) are valuable chemotaxonomic markers for *Corynebacterium* and related taxa (Minnikin et

al., 1978). They are unique lipophilic components of the cell envelopes of the genera *Corynebacterium*, *Gordona*, *Mycobacterium*, *Nocardia*, *Rhodococcus* and *Tsukamurella*. The most convenient method for the determination of mycolic acids (see Keddie and Jones, 1981 for an evaluation of the methods available) is the acid methanalysis of bacterial cells and subsequent thin layer chromatographic analysis of the resulting mycolic acid methyl esters (Minnikin et al., 1975; Minnikin et al., 1978).

The presence of mycolic acids is a criterion that allows the genera mentioned above to be separated from all other bacteria of similar coryneform morphology. Also, mycolic acid-containing genera can be differentiated to a certain degree by examining the size of these compounds (see Collins and Cummins, 1986b). However, part of *Rhodococcus* overlaps with *Corynebacterium* with respect to the mycolate sizes (Collins et al., 1982b), which may pose problems. With the exception of *C. amycolatum*, which does not contain mycolic acids (Collins et al., 1988), all bacterial species discussed in this chapter have mycolic acids with 26–38 carbon atoms (Minnikin et al., 1978; Lanéelle et al., 1980).

DIFFERENTIATION AT THE SPECIES LEVEL Biochemical characteristics that may be useful for differentiating saprophytic *Corynebacterium* species are listed in Table 1.

Preservation

Strains of *Corynebacterium* grown on agar slants or plates can be kept at 4°C for at least 4–6 weeks. Collins and Cummins (1986b) reported that cultures grown in chopped meat medium (without glucose) will remain viable for many months if stored in the dark at room temperature. Long-term storage can be achieved by adding 20% glycerol or 7% dimethylsulfoxide (DMSO) to liquid cultures and freezing at –70°C. Lyophilization is also a reliable means of long-term preservation. For this purpose, we harvest 10 ml of overnight cultures grown in the *Corynebacterium* medium described above, resuspend the cells in 1 ml of 10% skim milk (Difco) and, upon lyophilization of 0.2 ml aliquots, store them over silica gel in sealed glass tubes.

Cell Wall Characteristics

The chemical nature of the major constituents of the cell walls of corynebacteria and related genera has been the subject of many studies (Minnikin et al., 1978; Collins et al., 1982b; Minnikin and O'Donnell, 1984; Daffe and Draper, 1998). The peptidoglycan is directly crosslinked (A1γ-

type; Schleifer and Kandler, 1972) with *meso*-diaminopimelic acid (*meso*-A₂pm). An arabinogalactan polysaccharide, which is partially esterified by a special class of lipids, i.e., the mycolic acids, is covalently linked to the peptidoglycan. The arabinan and galactan segments of the *Corynebacterium* arabinogalactan also contain significant amounts of mannose and glucose substituents. Additionally, high- and low-molecular-mass glucan, arabinomannan, lipoglycans, and a protein surface layer are present in the cell wall of corynebacteria (Peyret et al., 1993; Sutcliffe, 1995; Soual-Hoebeke et al., 1999; Puech et al., 2001).

Interestingly, molecular biological, biochemical and ultrastructural studies recently showed that the architecture and function of the cell wall of the Gram-positive corynebacteria quite closely resemble those of the Gram-negative cell envelope, although the molecular details are strikingly different. Typical Gram-negative bacteria are characterized by an outer membrane which is a lipid bilayer composed of phospholipids and lipopolysaccharides. In *Corynebacterium* and related Gram-positive bacteria, it appears that the covalently linked mycolic acids, together with free mycolates (trehalose dicorynemycolates and trehalose monocorynemycolates) and phospholipids, form an outer membrane-like diffusion barrier (Fig. 3). Evidence that this barrier could represent a lipid bilayer was obtained with freeze-etch electron microscopy techniques that revealed a main fracture plane within the cell wall of corynemycolate-containing strains of corynebacteria. The mycolate-less cells of *C. amycolatum* strains, on the other hand, exhibited a fracture plane only within the cytoplasmic membrane (Puech et al., 2001). Mutants defective in protein components involved in extra-cytoplasmic lipid metabolism (mycoloyl transferases) displayed a decreased mycolate

content and an altered cell wall permeability, which points to an important role of the mycolic acids for the outer membrane-like barrier (Jackson et al., 1999; Puech et al., 2000).

The hypothesis of a closed outer membrane bilayer in corynebacterial cells (Puech et al., 2001; Fig. 3) demands a specific mechanism(s) for the transport of hydrophilic solutes across this barrier. Indeed, channel-forming activity in the cell wall of *C. glutamicum* was described by Niederweis et al. (1995), indicating a hydrophilic pathway through the mycolic acid-containing layer—an observation made previously also in mycobacteria. Recently, pore-forming proteins of corynebacteria, nocardiae and mycobacteria have been described. In contrast to the typical trimeric porins of the Gram-negative outer membranes, the porins of *Corynebacterium* strains are low-molecular-mass peptides that can form ion-permeable channels (Mukhopadhyay et al., 1997; Lichtinger et al., 1998; Lichtinger et al., 1999; Kartmann et al., 1999; Rieß et al., 1999). These recent findings about the cell wall structure have important implications for many aspects of corynebacterial biology, including solute uptake and excretion, cell surface properties, susceptibility to antibacterial compounds, etc. They also explain why corynebacteria are relatively poor in the secretion of proteins (Liebl and Sinskey, 1988; Liebl et al., 1989c).

Genetics

The industrial interest in corynebacteria has led to the development of cloning systems for these bacteria, mainly of *C. glutamicum* and closely related organisms. As a prerequisite for the construction of cloning vectors, numerous corynebacterial strains were screened for the presence of plasmids. Plasmids were detected in strains of medically significant and nonmedical corynebac-

Fig. 3. Hypothetical model of the cell envelope of typical mycolic acid-containing corynebacteria. The model as described by Puech et al. (2001) is based on the chemical analysis of cell walls, biochemical and biophysical characterization of cell wall proteins, and ultrastructural studies including transmission electron microscopy and freeze-etch electron microscopy, mainly of corynebacteria and mycobacteria. The bilayer nature of the outer membrane, and the depicted organization of pore-forming proteins spanning all layers of the cell envelope, are speculative (see text).

teria, i.e., *C. diphtheriae*, *C. glutamicum*, "*B. lactofermentum*," *C. callunae*, "*C. lilium*," "*C. melassecola*," *C. renale* and *C. xerosis*, with sizes ranging between about 1.4 and 95 kilobases (Miwa et al., 1984; Katsumata et al., 1984; Sandoval et al., 1984; Sandoval et al., 1985; Yoshihama et al., 1985; Serwold-Davis et al., 1987; Sonnen et al., 1991; Takeda et al., 1990; Nath and Deb, 1995; Deb and Nath, 1999). Interestingly, certain plasmids of *Brevibacterium linens* function in *Corynebacterium* species (Ankri et al., 1996a). Apart from a few plasmids carrying antibiotic resistance determinants (Katsumata et al., 1984; Tauch et al., 1995), most of the known corynebacterial plasmids are cryptic. The *C. glutamicum* plasmid pCG4 was reported to carry an integron (Nesvera et al., 1998). A multitude of cloning vectors for amino acid-producing corynebacteria have been constructed, most of which are shuttle vectors based on cryptic corynebacterial plasmids (Martin et al., 1987; Archer et al., 1989; Eikmanns et al., 1991; Jakoby et al., 1999).

Several methods for the introduction of recombinant plasmid molecules in corynebacteria are available. Protoplast transformation, a method established for use with various other Gram-positive host organisms, was developed for amino acid-producing corynebacteria simultaneously by different groups (Katsumata et al., 1984; Santamaria et al., 1984; Yoshihama et al., 1985). In these transformation systems, not genuine (spherical) protoplasts are used, but osmotically sensitive cells that retain rod-shaped morphology. Electroporation was shown to be a more convenient and much more efficient method for transformation of *C. glutamicum* (Liebl et al., 1989a; Haynes and Britz, 1989; Dunican and Shivan, 1989; Bonamy et al., 1990). Finally, the conjugal transfer of mobilizable shuttle plasmids from Gram-negative *Escherichia coli* to various corynebacterial strains was described as a further method for gene transfer into *Corynebacterium* (Schäfer et al., 1990). Besides introducing and establishing autonomously replicating multicopy plasmids in corynebacterial cells, methods are available for the integration, deletion or replacement of DNA sequences in the chromosome of *Corynebacterium*. For this purpose, typically, nonreplicative vectors carrying DNA segments homologous to specific regions of the chromosome are mobilized or electroporated into *Corynebacterium* cells, and chromosomal integration occurs via homologous recombination (Schwarzer and Pühler, 1991; Reyes et al., 1991; Schäfer et al., 1994b). In addition, a method for the chromosomal integration of replicative plasmid DNA was described by Ikeda and Katsumata (1998). Finally, chromosomal integration of vectors via

short homologous sequences of 8–12 bp, presumably by virtue of a RecA-independent illegitimate recombination mechanism, was reported to occur at low frequencies (Mateos et al., 1996).

Numerous observations made during transformation experiments suggest the wide dissemination of restriction/modification systems in corynebacteria (e.g., Follettie and Sinskey, 1986; Katsumata et al., 1984; Bonamy et al., 1990; Vertes et al., 1993c; Vertes et al., 1993b; Ankri et al., 1996b). The problems posed by these systems for cloning experiments can be overcome by the use of restriction-deficient host strains (Liebl et al., 1989a; Bonnassie et al., 1990; Liebl and Schein, 1990; Schäfer et al., 1990; Schäfer et al., 1994a). In some strains, inactivation of the host cell restriction system by treatment of the cells with stress factors such as heat (Schäfer et al., 1994a; van der Rest et al., 1999), or the use of unmethylated DNA for transformation (Ankri et al., 1996b), has been shown to be useful to avoid host cell restriction of incoming DNA.

Polyethylene glycol (PEG)-induced protoplast fusion has been used to obtain hybrid organisms from mutant strains of amino acid-producing corynebacteria (Kaneko and Sakaguchi, 1979; Karasawa et al., 1986) and may have potential in the breeding of improved industrial amino acid producers. However, since it is a rather nonspecific method, its usefulness in basic research is limited.

Phages of several amino acid-producing corynebacteria (*C. glutamicum*, *C. lilium*, *B. lactofermentum*, *B. flavum*) have been described (Oki and Ogata, 1968a; Patek et al., 1985; Trautwetter et al., 1987; Sonnen et al., 1990). Certain phages have been used in transfection experiments with protoplasts of amino acid-producing corynebacteria to optimize protoplast transformation protocols (Katsumata et al., 1984; Sanchez et al., 1986; Yeh et al., 1985). Phage-mediated transduction in *B. flavum* was reported by Momose et al. (1976). A cosmid vector for glutamic acid-producing bacteria has been constructed that was transduced at low frequency through phage infection (Miwa et al., 1985). However, presently too little is known about the biology of the bacteriophages of saprophytic corynebacteria to allow their exploitation as tools in genetic research.

Most genes introduced into amino acid-producing corynebacteria by recombinant DNA methods are homologous genes from these bacteria themselves, encoding enzymes involved in amino acid biosynthesis or deregulated derivatives thereof. Using this strategy, one hopes to obtain improved production strains by raising the activity of rate-limiting enzymes and thus removing bottlenecks of amino acid biosynthesis. On the other hand, heterologous expression

signals are readily utilized by corynebacteria, making these organisms versatile hosts for recombinant gene expression. Heterologous antibiotic resistance genes of Gram-negative (*Escherichia coli*) and Gram-positive origin (*Staphylococcus aureus*, *Enterococcus faecalis*, *Streptomyces acrimycini* and *Streptomyces hygroscopicus*) were observed to function in *C. glutamicum* (*B. lactofermentum*; Ozaki et al., 1984; Batt et al., 1985; Yoshihama et al., 1985; Santamaria et al., 1984; Santamaria et al., 1987). Additionally, a number of other heterologous genes have been expressed in these bacteria, e.g., lactose utilization genes from *Escherichia coli* (Brabetz et al., 1991; Brabetz et al., 1993), threonine biosynthetic genes from *E. coli* (Patek et al., 1989), ovine γ -interferon (Billman-Jacobe et al., 1994), proteases (Billman-Jacobe et al., 1995), an α -amylase gene from *Bacillus amyloliquefaciens* (Smith et al., 1986), exoglucanase and endoglucanase A genes from *Cellulomonas fimi* (Paradis et al., 1987), and the genes encoding thermonuclease from *Staphylococcus aureus* and lipase from *Staphylococcus hyicus* (Liebl et al., 1989c). The extracellular enzymes encoded by the *Cellulomonas* and *Staphylococcus* genes are secreted to the culture medium by the corynebacterial hosts (Paradis et al., 1987; Liebl et al., 1989c; Liebl et al., 1992a). Furthermore, the *E. coli* lac, lacUV5, tac, and trp promoters are functional in *C. glutamicum* ("*B. lactofermentum*"; Morinaga et al., 1987; Brabetz et al., 1991; Eikmanns et al., 1991; Liebl et al., 1992b). The broad recognition of heterologous expression signals by *C. glutamicum* contrasts with the situation found with other Gram-positive cloning hosts, e.g., *Bacillus subtilis*, where genes of Gram-negative origin are generally not efficiently expressed due to more stringent requirements of the respective Gram-positive transcription/translation apparatus (McLaughlin et al., 1981; Moran et al., 1982; Graves and Rabinowitz, 1986). Patek et al. (1996) undertook a detailed survey of promoter sequences from *C. glutamicum*. This study showed that a corynebacterial promoter consensus can be deduced which is similar to the consensus pattern recognized by the major RNA polymerase σ -factor (σ^{70}) of *E. coli*. The conserved -35 and -10 sequences of *C. glutamicum* promoters were found to be tttGcca.a and ggTA.aaT, respectively, with the core consensus hexamer motifs being ttGcca and TA.aaT, respectively. The -10 region appears to play the predominant role in corynebacterial promoter recognition, whereas the -35 hexamer motif is less conserved than in other bacteria (Patek et al., 1996). This conclusion is in accordance with the observation that a mutation in the -10 region of the *E. coli* lac promoter from TATGTT to TATATT improved

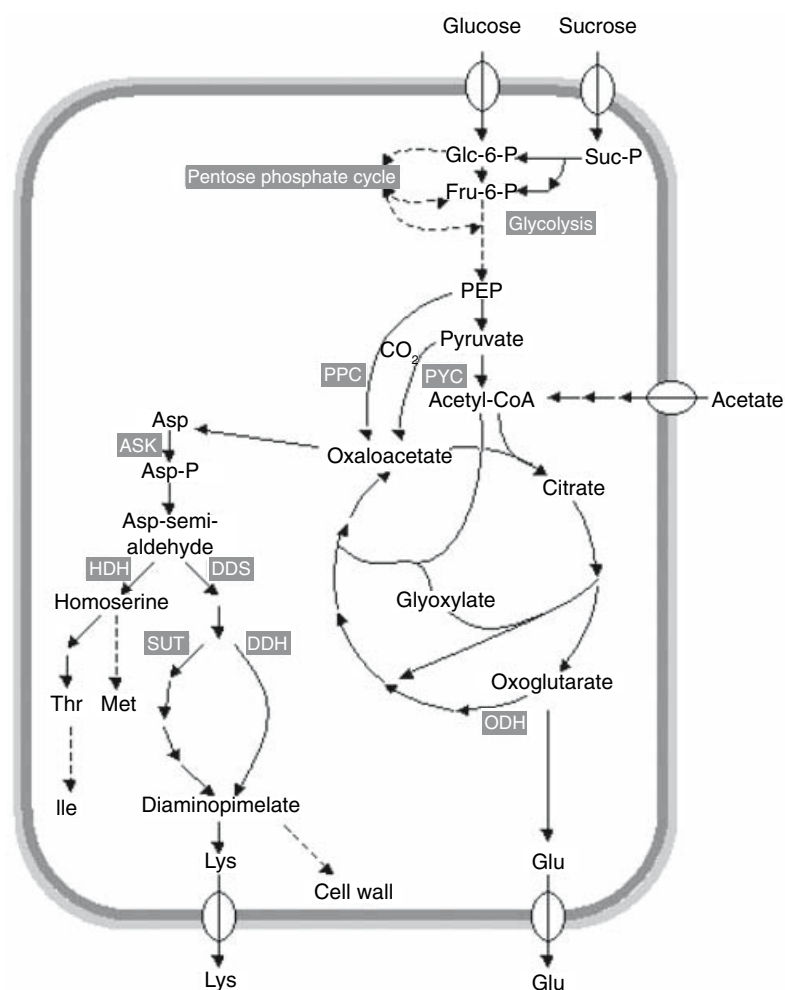

the efficiency of this promoter in *C. glutamicum* (Brabetz et al., 1991).

The biotechnological importance of amino acid-producing corynebacteria (see below) also has led to a pronounced interest in the genetic capacity of *C. glutamicum*. As a consequence, the nucleotide sequence of the genome of *C. glutamicum* has been determined several times by consortia of research groups and different companies in the past few years. Nevertheless, as of 2001, no complete genome sequence is available in the publicly accessible sequence databases. The genome size is about 3.08 Mbp (Bathe et al., 1996). Various transposable elements are known to exist in the genome of *C. glutamicum* strains. Five insertion (IS) elements have been detected in different strains (IS family affiliation and *C. glutamicum* strain(s) in parentheses): IS1206 (IS3 family; ATCC21086; Bonamy et al., 1994), IS31831 (ISL3 family; ATCC31831; Vertes et al., 1994), IS13869 (ISL3 family; ATCC13869; Correia et al., 1996), ISCg1 (ISL3 family; type strain ATCC13032; Jäger et al., 1995), and ISCg2 (IS30 family; type strain ATCC13032, ATCC13869, and ATCC14020; Quast et al., 1999). It is noteworthy in this context that transposons bearing antibiotic resistance determinants from other *Corynebacterium* species are capable of transposition in *C. glutamicum* (Tauch et al., 1995; Tauch et al., 1998).

Physiology

Little effort has been devoted to the metabolism of saprophytic corynebacteria. Only amino acid-producing corynebacteria, particularly *C. glutamicum* (including "*Brevibacterium flavum*"), have been studied in more detail. In "*B. flavum*," the uptake of glucose and fructose seems to be catalyzed by specific phosphoenolpyruvate:sugar phosphotransferase (PTS) systems (Mori and Shiiro, 1987a; Mori and Shiiro, 1987b), although conflicting data have been presented by Marauska et al. (1981). The main routes for hexose breakdown in amino acid-producing corynebacteria are the Embden-Meyerhof-Parnas and the pentose phosphate pathways followed by further oxidation through the tricarboxylic acid cycle (Fig. 4). Maltose and sucrose are cleaved intracellularly in "*B. flavum*" by maltase and invertase, respectively. The catabolism of mannitol is initiated by mannitol dehydrogenase. Ribose and gluconate are assimilated via the pentose phosphate pathway (Mori and Shiiro, 1987b). It has been demonstrated that after internalization into *C. glutamicum* cells, acetate is utilized by acetate kinase (Ack) and phosphotransacetylase (Pta; Reinscheid et al., 1999), the key enzymes of the glyoxylate pathway, which is necessary as an anaplerotic

Fig. 4. Schematic of metabolic pathways leading to glutamate and lysine in *Corynebacterium glutamicum*. Key enzymes discussed in the text are: ASK, aspartate kinase; DDH, diaminopimelate dehydrogenase; DDS, dihydrodipicolinate synthase; HDH, homoserine dehydrogenase; ODH, 2-oxoglutarate dehydrogenase; PPC, phosphoenolpyruvate carboxylase; PYC, pyruvate carboxylase; and SUT, succinyl transferase.

sequence for the assimilation of this C_2 compound (Shiio et al., 1959). The glyoxylate cycle enzymes isocitrate lyase (AceA) and malate synthase (AceB) are allosterically controlled by intermediates of central metabolism, and their synthesis is regulated at the transcriptional level (Reinscheid et al., 1994a; Reinscheid et al., 1994b). Finally, amino acid-producing corynebacteria are able to assimilate various organic acids and ethanol (Oki et al., 1968b; Yamada and Komagata, 1972b).

Corynebacterium glutamicum and similar bacteria are used for the fermentative production of amino acids, with L-glutamic acid and L-lysine being the most important as far as quantity is concerned. Since the biosynthetic pathways in *C. glutamicum* and similar bacteria are basically the same as found in other organisms, the question arises which peculiarities make these bacteria superior amino acid excreters. Some features of the metabolism related to the high-level amino acid production by *C. glutamicum* and related organisms are discussed below.

As a soil bacterium, *C. glutamicum* needs to cope with osmotic changes caused by variations in the availability of water. Also in industrial amino acid production processes, this organism is confronted with significant variations in the osmolality of the surrounding media (high sugar concentration at the beginning and high amino acid concentration towards the end of the process). To this end, Krämer and coworkers have characterized four secondary carriers for the uptake of different compatible solutes (i.e., betaine, proline and ectoine), and for the rapid efflux of solutes, they have characterized osmo-regulated channels, which (under hypo-osmotic conditions) may be mechanosensitive ion channels in the cytoplasmic membrane (see Peter et al. [1998]; Ruffert et al., 1997; Ruffert et al., 1999).

Applications

AMINO ACID FERMENTATIONS Certain saprophytic corynebacteria have a long tradition as industrial microorganisms in biotechnological production

processes. The most prominent example is the production of amino acids by *C. glutamicum* and other similar bacteria. The worldwide production of amino acids amounts to more than 10^9 kg per year. Two of the most important amino acids in terms of quantity, i.e., L-glutamic acid and L-lysine, are produced fermentatively on a large scale by *C. glutamicum*. *Corynebacterium glutamicum* (synonym "*Micrococcus glutamicus*") was first isolated in 1957 by Kinoshita while searching for an efficient glutamic acid-producing microorganism among bacterial isolates (Kinoshita and Nakayama, 1978). Subsequently, a large number of glutamic acid producers were isolated and classified in different genera as various different species, e.g., "*Brevibacterium flavum*," "*B. lactofermentum*," "*B. roseum*," "*B. divaricatum*," "*C. lilium*," "*C. herculis*," "*Microbacterium ammoniophilum*," etc. However, the separate species status of these organisms is in serious doubt (see introduction to this chapter), and some of these organisms carry invalid names, while others have been reclassified as *C. glutamicum* (Liebl et al., 1991).

Worldwide production of monosodium glutamate (MSG), which has a meaty taste and is used mainly as a flavoring agent, was estimated at approximately $6\text{--}8 \times 10^8$ kg (Leuchtenberger, 1996; Demain, 2000). Under certain culture conditions, *C. glutamicum* excretes remarkably large amounts of glutamic acid into the growth medium (>100 g per liter). In typical fermentations, the molar yield of glutamate from sugar is 0.50–0.75 (Kinoshita and Nakayama, 1978; Demain, 2000). It has been known for a long time that glutamate excretion is coupled with alterations in the cell membrane (Takinami et al., 1968; Hoischen and Krämer, 1990). However, in contrast to previous long-held beliefs (Shiio et al., 1963; Kimura, 1963; Demain and Birnbaum, 1968), glutamate excretion does not occur as a consequence of mere leakiness of the cells via relaxed membrane permeability (Hoischen and Krämer, 1989; Krämer, 1994a; Krämer, 1994b). Also, glutamate excretion by producing *C. glutamicum* cells is not achieved by the reverse action of the glutamate uptake system present in this organism, as was suggested by Clement et al. (Clement et al., 1984; Clement et al., 1986), since glutamate uptake proceeds via a primary active system that is not reversible (Krämer, 1994a; Kronmeyer et al., 1995). Instead, a specific transport system responsible for glutamate excretion by *C. glutamicum* under biotin limitation was described by Hoischen and Krämer (1989). This efficient efflux system for glutamate, which is energy-dependent and functions against an existing chemical gradient (Gutman et al., 1992), is thought to be a key player in glutamic acid overproduction.

In industrial glutamic acid fermentations, membrane alterations and glutamate excretion are often brought about by biotin limitation in the culture broth. The concentration of biotin for optimal glutamate accumulation is approximately 1 $\mu\text{g/liter}$ (Kinoshita and Tanaka, 1972; Hoischen and Krämer, 1989). *Corynebacterium glutamicum* and similar amino acid-producing bacteria are biotin auxotrophs, and biotin limitation leads to suboptimal growth and gives rise to alterations in the lipid content and composition of the cell membrane by interfering with fatty acid synthesis (Takinami et al., 1968; Hoischen and Krämer, 1990). It is, however, not clear how biotin starvation actually triggers glutamate excretion. With an experimental setup which employs monitoring the lipid composition and glutamate excretion activity, upon adding biotin to biotin-limited (glutamate-producing) cells, it was observed that changes in glutamate excretion can be provoked on a much shorter time scale than significant alterations in the lipid content and composition take place (Hoischen and Krämer, 1990). Therefore, it was concluded that the decreased lipid content of the membrane, although a necessary prerequisite, is not sufficient for high glutamate efflux activity by the carrier (Hoischen and Krämer, 1990). Possible components of biotin-dependent acyl-CoA carboxylase activities have been found (DtsR1, DtsR2 and AccBC) which are necessary for the synthesis of fatty acids and mycolates and which are likely to be involved in the chain of events leading to membrane alterations and glutamate efflux under biotin limitation (Kimura et al., 1996; Kimura et al., 1997; Jäger et al., 1996; Eggeling and Sahl, 1999).

For the use of cheap substrates rich in biotin, e.g., cane molasses, and for glutamic acid fermentation, other processes that function independent of biotin limitation have been developed. The addition of penicillin during the logarithmic growth phase leads to effective glutamate excretion. This treatment does not provoke cell lysis but causes a rapid, 97–99.5% decrease in cell viability (Kinoshita, 1985). Alternative methods include the addition of fatty acid derivatives such as polyoxyethylene sorbitan monooleate (Tween 60) during growth or the use of oleic acid or glycerol-requiring auxotrophs which are kept under oleic acid or glycerol limitation, respectively, during fermentation (Kinoshita and Nakayama, 1978). In small-scale experiments, high glutamate excretion activity was also brought about by the addition of amine surfactants (Dupperay et al., 1992) or by adding local anesthetics like tetracaine at concentrations known to alter the membrane fluidity (Krämer, 1994a).

Another factor long suspected to be involved in the triggering of glutamate production is the activity of oxoglutarate dehydrogenase. However, the

traditional idea that oxoglutarate dehydrogenase is absent in *C. glutamicum* is clearly not true (Shiio and Ujigawa-Takeda, 1980). This fact is in accordance with results showing that 1) *C. glutamicum* can grow well on L-glutamate, and 2) when the glyoxylate cycle is not active, cells are still able to grow rapidly, with complete oxidation of glucose to carbon dioxide. The oxoglutarate dehydrogenase complex appears to have an unusual structure in *C. glutamicum* (Usuda et al., 1996). Interestingly, under conditions of glutamate excretion, the activity of this enzyme is reduced by 90%, which favors glutamate production by the enzyme competing for the same substrate as oxoglutarate dehydrogenase and glutamate dehydrogenase. Inactivation of *odhA*, the gene for one subunit of the oxoglutarate dehydrogenase in the wild type of *C. glutamicum*, leads to high-level glutamate excretion, even without biotin limitation (Kawahara et al., 1997). A comprehensive, recent overview of factors linked with the still puzzling phenomenon of glutamate efflux was given by Eggeling and Sahm (1999).

Another amino acid that is produced fermentatively with *C. glutamicum* and similar bacteria is L-lysine (estimated annual production 2.5 (10^8 kg). In industrial production plants, the concentration of lysine in the fermentation broth can reach up to 120–170 g/liter at the end of the process (Eggeling and Sahm, 1999; Demain, 2000), with molar yields of L-lysine from glucose of 0.25–0.35. L-Lysine is an essential amino acid, which is used mainly as an animal feed supplement, and far smaller amounts are produced for the pharmaceutical and cosmetics industries. The sequence of biosynthetic reactions leading to the production of L-lysine from aspartate is part of a branched pathway that also produces threonine, isoleucine, and methionine, all members of the so-called “aspartate family of amino acids” (Fig. 4). Unusually, the biosynthesis of DL-diaminopimelate, which is needed as the precursor of L-lysine as well as for cell wall peptidoglycan synthesis, occurs via a split pathway in *C. glutamicum*. The common part of these pathway variants consists of the activation and subsequent reduction of aspartate to aspartate semialdehyde by aspartate kinase (LysC) and aspartate semialdehyde dehydrogenase (Asd), followed by conversion of aspartate semialdehyde to piperidine dicarboxylate via dihydrodipicolinate with dihydrodipicolinate synthase (DapA) and dihydrodipicolinate reductase (DapB). Both the succinylase and the dehydrogenase pathway are present for the conversion of piperidine dicarboxylate to DL-diaminopimelate (Schrumpf et al., 1991). Whereas the latter branch is a one-step reaction with D-diaminopimelate dehydrogenase (Ddh), the succinylase branch proceeds via four steps with succinylated intermediates. The dehydrogenase

variant is energetically less expensive than the succinylase variant. However, owing to the low affinity of the dehydrogenase towards ammonium, the dehydrogenase branch is not operational at low ammonium concentrations, and under these conditions the succinylase branch must be used for DL-diaminopimelate synthesis (Sonntag et al., 1993). Although not essential for L-lysine synthesis, inactivation of the dehydrogenase leads to reduced lysine production (Schrumpf et al., 1991). It is clear from metabolic flux analyses that lysine-producing *C. glutamicum* strains can use both pathways simultaneously. However, while strain MH20-22B grown in continuous culture synthesized 26% of lysine via the dehydrogenase reaction, strain ATCC21253 grown in batch culture displayed a higher proportion of lysine synthesis (63%) through this route (Marx et al., 1996; Wittmann and Heinzle, 2001). Although strain differences may play a role, the main reason for this discrepancy probably lies in the different cultivation conditions. It is known that the flux partitioning between the two pathways of DL-diaminopimelate synthesis depends on the supply of ammonium, leading to a relative contribution of the dehydrogenase pathway to lysine synthesis between 0 and 72% (Sonntag et al., 1993; Eggeling and Sahm, 1999).

While glutamic acid production by *C. glutamicum* can be achieved simply by adjusting the critical culture parameters (biotin limitation, addition of penicillin, etc., see above), leading to a “metabolic overflow” situation and active glutamate efflux, the high-yield fermentation of lysine by this organism requires the use of mutated or genetically modified strains. To understand the reasons that may make amino acid-producing corynebacteria so well suited for the overproduction of L-lysine, it is important to realize the relative simplicity of regulation found in this multibranched biosynthetic pathway when compared with the situation found in other bacteria like *E. coli*. There is no regulation of the synthesis of the lysine-specific enzymes within the biosynthetic routes of the aspartate family in *C. glutamicum* (Yeh et al., 1988). Homoserine dehydrogenase, the enzyme located at the branching point leading to threonine, isoleucine and methionine, is repressed by methionine (Nara et al., 1961; Cremer et al., 1988). Inhibition of enzyme activity in the lysine biosynthetic sequence was only found for aspartate kinase (Nakayama et al., 1966; Cremer et al., 1988), the first step of the entire aspartate family branched pathway. In contrast to *E. coli*, which contains three different aspartate kinase isoenzymes (two of which are bifunctional proteins displaying aspartate kinase plus homoserine dehydrogenase activity; Cohen, 1983) that are each regulated by a different end product, *C. glutamicum* has only a

single aspartate kinase. Feedback inhibition of this enzyme occurs by the concerted action of lysine plus threonine. This type of regulation represents a means for overall control of the synthesis of the amino acids of both major branches of the pathway. The flow of aspartate semialdehyde to either the diaminopimelate/lysine or the methionine/threonine/isoleucine branch is regulated solely at the level of homoserine dehydrogenase, the initial enzyme of the latter branch, by repression of the enzyme by methionine and sensitive feedback inhibition by threonine. Additionally, homoserine dehydrogenase activity is inhibited 50% by L-isoleucine (Cremer et al., 1988). There is no regulation of dihydrodipicolinate synthase, the other enzyme at the branching point competing for aspartate semialdehyde and the initial enzyme of the diaminopimelate/lysine-specific part of the pathway. Accumulation of threonine efficiently shuts down the methionine/threonine/isoleucine branch by sensitive feedback inhibition of homoserine dehydrogenase, directing the flow of aspartate semialdehyde into the lysine branch. Excess lysine in turn can lead to the decrease of carbon flow into the whole biosynthetic pathway via the multivalent inhibition of aspartate kinase by lysine plus threonine. The rather simple regulation strategies found in amino acid-producing corynebacteria and the lack of additional and differentially regulated isoenzymes at crucial nodes of the biosynthetic pathways (for example, as noted above, *E. coli* has three distinct and separately regulated aspartate kinase isoenzymes) may explain the relative ease of obtaining high-level lysine-producing *C. glutamicum* strains. Because of the lack of regulation of the initial enzymes of the diaminopimelate/lysine branch, a relatively simple way to obtain a lysine overproducer is to genetically knock out homoserine dehydrogenase, which leads to the shut-down of the methionine/threonine/isoleucine branch. In 1958, Kinoshita et al. isolated such homoserine- or both methionine plus threonine-requiring mutants of *C. glutamicum* that produced L-lysine from carbohydrate (Kinoshita et al., 1958). Such threonine- and methionine-requiring strains produce lysine if threonine is supplemented at a limiting concentration, because a low intracellular threonine level bypasses the concerted feedback inhibition of aspartate kinase. A different strategy used to obtain lysine-producing strains employs the selection of regulatory mutants that display an increased resistance to antimetabolites. Isolation of *C. glutamicum* mutants resistant to the lysine analogues S-(2-aminoethyl)-L-cysteine (AEC) or O-(2-aminoethyl)-L-serine ("oxalysine") leads to strains with increased lysine production due to the release of feedback inhibition of the first step of lysine synthesis from aspartate. These mutants contain a deregulated aspartate kinase that is no

longer subject to the concerted feedback inhibition by lysine plus threonine (Shiio and Sano, 1969; Sano and Shiio, 1970; Schrumpf et al., 1992; Jetten et al., 1995; Leuchtenberger, 1996). Industrial strains used for the production of amino acids often have combinations of auxotrophic and regulatory mutations (see Leuchtenberger, 1996).

L-Lysine excretion, like glutamate excretion, is via active transport and involves a specific carrier. However, in this case the mechanism is secondary active transport using a (2OH⁻)-lysine symporter (Bröer and Krämer, 1991; Krämer, 1994a; Krämer, 1994b). The lysine export carrier LysE is needed during growth on lysine-containing peptides, to avoid the accumulation of lysine in the cell. In the presence of lysyl-alanine, the intracellular lysine concentration in a LysE-deficient mutant can reach more than 1 M, and growth inhibition is observed (Vrljic et al., 1996). Strikingly, the lysine secretion system of certain production strains has been shown to be regulated differently and to display kinetic properties different from the wild type (Bröer et al., 1993), indicating the importance of efficient lysine export for its fermentative overproduction.

Much attention has been paid to the central metabolism of *C. glutamicum*, which provides the precursors of amino acid biosynthesis, particularly in the past few years using modern techniques of metabolic flux analysis. During both L-glutamic acid and L-lysine production from glucose, the major flow of carbon is channeled through the pentose phosphate pathway (Dominguez et al., 1998; Wittmann and Heinzle, 2001). For example, during the lysine-production phase of strain ATCC 21253 grown in batch culture, only 24.4% of the incoming glucose was routed directly into glycolysis while 71% of the incoming carbon entered the central metabolism via the oxidative part of the pentose phosphate pathway, thus supplying ample amounts of NADPH (together with the isocitrate dehydrogenase reaction of the citric acid cycle, even an excess of NADPH) for lysine biosynthesis (Wittmann and Heinzle, 2001).

An important factor for the overproduction of L-glutamate as well as L-lysine is the replenishment of intermediates of the citric acid cycle withdrawn for their synthesis, i.e., 2-oxoglutarate and oxaloacetate, respectively. To this end, *C. glutamicum* possesses two enzymes which ensure the continuous supply of oxaloacetate to the citric acid cycle during growth on glucose: phosphoenolpyruvate (PEP) carboxylase and pyruvate carboxylase (Eikmanns et al., 1989; Jetten et al., 1994; Mori and Shiio, 1985a; Mori and Shiio, 1985b; Ozaki and Shiio, 1969; Peters-Wendisch et al., 1996, 1997, 1998; Fig. 4). Phosphoenolpyruvate carboxykinase, another activity with anaplerotic potential present in *C. glutamicum*, is completely inhibited in the direction of oxaloacetate synthesis

by low concentrations of ATP (Jetten and Sinskey, 1993) and therefore is thought to function mainly in gluconeogenesis rather than in anaplerosis. Finally, the glyoxylate cycle, which is used as an anaplerotic sequence by some bacteria during growth on glucose, is needed for anaplerosis during growth of *C. glutamicum* on acetate but is also not required for anaplerosis during glucose consumption since its activity is tightly downregulated in glucose-grown cells (Reinscheid et al., 1994b), and mutants of a lysine-producing strain defective in the glyoxylate cycle enzyme isocitrate dehydrogenase are not affected in their growth on glucose or in their lysine productivity (Peters-Wendisch et al., 1996). Also, PEP carboxylase-negative mutants of *C. glutamicum* grow normally and are able to produce lysine on various media (Gubler et al., 1994; Peters-Wendisch et al., 1993; Peters-Wendisch et al., 1996), which demonstrates that this enzyme is dispensable for *C. glutamicum* and its loss can be compensated by pyruvate carboxylase. Pyruvate carboxylase mutants, on the other hand, although able to grow on glucose and acetate, cannot grow on lactate or pyruvate, indicating that pyruvate carboxylase is the crucial anaplerotic activity during growth on these C₃-compounds (Peters-Wendisch et al., 1997). If both the PEP carboxylase and the pyruvate carboxylase activities are deleted, *C. glutamicum* can no longer grow on glucose (Peters-Wendisch et al., 1998). Interestingly, recent metabolic flux analyses of glutamate and lysine producers revealed that in addition to the anaplerotic carboxylation, also decarboxylation of C₄ units happens to a certain extent in vivo, leading to a continuous depletion of these C₄ intermediates from the citric acid cycle. Thus, there is a significant backward flux from C₄ units of the citric acid cycle to C₃ units of glycolysis, implying a waste of ATP via a “futile cycle” at the anaplerotic node (Marx et al., 1996; Wittmann and Heinzle, 2001). Under conditions of glutamate production, however, the exchange flux between C₄ unit generation and decarboxylation is largely reduced (see Eggeling and Sahm, 1999).

Besides glutamate and lysine producers, *C. glutamicum* strains have been constructed which hyperproduce other amino acids, e.g., threonine, isoleucine, tyrosine, phenylalanine, or tryptophan (Kinoshita and Nakayama, 1978; Kinoshita, 1985; Katsumata and Ikeda, 1993; Sahm et al., 1995; Leuchtenberger, 1996). Traditionally, strains suited for amino acid production have been obtained by multiple rounds of classical random mutagenesis and screening procedures. Although this approach has proved to be very efficient and has led to amino acid producers with remarkable productivities, further improvement is presently sought with more rational strategies and by the application of recombinant DNA technology with the aid of the transformation systems now avail-

able for corynebacteria. One example in this field is the construction of tryptophan-hyperproducing *C. glutamicum* strains, yielding 58 g/liter tryptophan by 1) deregulating and/or overexpressing the terminal pathways leading to tryptophan and serine (a substrate of the final reaction in the tryptophan pathway) and by 2) low-copy amplification of the transketolase gene to modify the pentose phosphate pathway for an improved supply of the aromatic biosynthesis precursor erythrose 4-phosphate (Ikeda and Katsumata, 1999). In parallel to using genetic engineering for strain improvement of corynebacteria, the focus of research is being extended to include additional aspects besides merely the sequence of biosynthesis reactions leading to a specific amino acid. In this way, one hopes to come to a broad understanding of fluxes and flux control in *Corynebacterium* central metabolism and of the regulation of expression of genes of importance for amino acid hyperproduction. To this end, metabolic flux analysis, using either in-vivo-NMR or MALDI-TOF mass spectrometry as an analytical tool, is being used to quantify intracellular flux distributions, to compare key fluxes in wild-type and mutant strains, and to develop mathematical models for the *C. glutamicum* central metabolism (Vallino and Stephanopoulos, 1993; Marx et al., 1996; Park et al., 1997; Wittmann and Heinzle, 2001). In addition, due to the availability of the *C. glutamicum* genome sequence, methods of post-genome-analysis, i.e., transcript profiling with DNA chip technology (Loos et al., 2001) or proteome analysis, are used to detect possible bottlenecks at the level of the regulation, biosynthesis and stability of enzymes important for amino acid production. Coupling of these modern analytical approaches with the recombinant DNA technology available (extrachromosomal and chromosomal) is expected to lead to the specific design of further improved strains.

NUCLEOTIDE FERMENTATIONS AND OTHER APPLICATIONS

Saprophytic corynebacteria are also used in the fermentative production of nucleotides, which are of interest primarily as flavor-enhancing additives in foods (Komata, 1976). Mutant strains of *C. glutamicum* have been selected which excrete the purine ribonucleoside 5'-monophosphates 5'-inosinic acid (IMP), 5'-xanthylic acid (XMP), and 5'-guanylic acid (GMP; Demain, 1978). Similarly, adenine-requiring mutants of *C. ammoniagenes* (previously designated *Brevibacterium ammoniagenes*, later transferred to the genus *Corynebacterium* by Collins, 1987b) were found to accumulate IMP in fermentations (Nara et al., 1967). Remarkably, intact wild-type cells of *C. ammoniagenes* are able to convert hypoxanthine to IMP, guanine to GMP,

GDP and GTP, and adenine to AMP, ADP and ATP (Nara et al., 1967, 1968a; Tanaka et al., 1968) by "salvage synthesis" reactions. In the case of IMP production, particularly the concentration of manganese ions (Mn^{2+}) was found to be of importance, as very low as well as excessive amounts of Mn^{2+} negatively affected IMP accumulation (Furuya et al., 1970; Nara et al., 1968b). In the presence of nonlimiting amounts of manganese, nucleotide production can be achieved by the addition of certain antibiotics or surfactants or the use of mutant strains that accumulate IMP under excess manganese conditions (Nara et al., 1969b; Furuya et al., 1969). Improved *C. ammoniagenes* mutants producing more than 20 g per liter of IMP were selected. These were leaky adenine-auxotrophic, manganese-insensitive, and guanine-auxotrophic, and they displayed increased IMP-excretion characteristics (Teshiba and Furuya, 1982; Teshiba and Furuya, 1984). A different method for IMP production is fermentative production of inosine with *C. ammoniagenes* mutants (which are also leaky adenine-auxotrophic and guanine-auxotrophic) followed by chemical phosphorylation of the nucleoside with phosphoryl chloride ($POCl_3$). Inosine productivity by *C. ammoniagenes* strains can exceed 30 g per liter (Kotani et al., 1978). Mori et al. (1997) recently described a new process for IMP production, in which inosine fermentation by *C. ammoniagenes* is followed by enzymatic phosphorylation via addition of recombinant guanosine/inosine kinase-overexpressing *E. coli* cells. During this coupled process, which is carried out in the presence of detergents for cell permeabilization, the *C. ammoniagenes* cells regenerate the ATP needed for the kinase reaction (Mori et al., 1997). Analogous coupled systems were used for the production of sugar nucleotides like UDP-galactose or UDP-N-acetylglucosamine (Koizumi et al., 1998; Tabata et al., 2000). For production of GMP, xanthosine 5'-monophosphate (XMP) produced fermentatively by an appropriate *C. ammoniagenes* mutant strain can be converted to GMP by addition of overexpressed XMP aminase (Fujio et al., 1997). *Corynebacterium ammoniagenes* also has been used for the production of ATP from adenine (Fujio and Furuya, 1983). In addition to the production of nucleotides from purine bases, *C. ammoniagenes* was found to be suited for the fermentative production of nicotinamide adenine dinucleotide (NAD) when cultured in medium containing adenine and nicotinic acid or nicotinamide. Nicotinic acid mononucleotide was produced if only nicotinic acid or nicotinamide was present (Nakayama et al., 1968). Finally, Koizumi et al. (2000) reported high-level production (more than 15 g per liter) of the vitamin riboflavin (vitamin B₂) by a metabolically engineered recombinant

strain of *C. ammoniagenes* with enhanced activities of riboflavin biosynthetic enzymes.

The Genus *Corynebacterium*—Medical

ALEXANDER VON GRAEVENITZ AND KATHRYN BERNARD

Phylogeny and Taxonomy

The genus *Corynebacterium* is a member of the class Actinobacteria (high G+C Gram-positive bacilli), subclass Actinobacteridae, order Actinomycetales, suborder Corynebacterineae and family Corynebacteriaceae, which also includes the genus *Turicella* (Stackebrandt et al., 1997). This designation is based on extensive 16S rRNA gene sequencing data which demonstrated that the genus *Corynebacterium* is most closely related to non-acid-fast, partially acid-fast or acid-fast genera of the suborder Corynebacterineae, which also includes the families (genus/genera) Dietziaceae (*Dietzia*), Gordoniaceae (*Gordonia* and *Skermania*), Mycobacteriaceae (*Mycobacterium*), Nocardiaceae (*Nocardia* and *Rhodococcus*), Tsukamurellaceae (*Tsukamurella*) and Williamsiaceae (*Williamsia*) (Funke et al., 1994; Pascual et al., 1995; Ruimy et al., 1995; Chun et al., 1997; Stackebrandt et al., 1997; Kämpfer et al., 1999).

Currently, the genus *Corynebacterium* consists of 59 validly described species, of which 35 species as well as two taxon groups are considered to be medically relevant and will be discussed in this chapter. These include *C. accolens*, *C. afermentans*, *C. amycolatum*, *C. appendicis*, *C. argentoratense*, *C. aurimucosum*, *C. auris*, *C. confusum*, *C. coyleae*, *C. diphtheriae*, *C. durum*, *C. falsenii*, *C. frenyi*, *C. glucuronolyticum*, *C. imitans*, *C. jeikeium*, *C. kroppenstedtii*, *C. lipophiloflavum*, *C. macginleyi*, *C. matruchotii*, *C. minutissimum*, *C. mucifaciens*, *C. mycetoides*, *C. propinquum*, *C. pseudodiphtheriticum*, *C. pseudotuberculosis*, *C. riegelii*, *C. simulans*, *C. singulare*, *C. striatum*, *C. sundsvallense*, *C. thomssenii*, *C. ulcerans*, *C. urealyticum* and *C. xerosis*, as well as Coryneform CDC groups G and F-1. A “black-pigmented *Corynebacterium* species” associated with human disease, but not as yet validated, is also described briefly here.

Valid *Corynebacterium* species not known to be isolated from diseased humans and most commonly recovered from soil, animals, the environment or foods are described further in another chapter (*Corynebacterium*–Nonmedical in this

Volume). The following 12 mostly nonhuman taxa have an internet or literature presence, but have not been validated: *C. acetoacidophilum*, *C. cervicis*, *C. crenatum*, *C. fastidiosum*, *C. genitalium*, *C. melassecola*, *C. nephridii*, *C. nigricans* (the “black-pigmented *Corynebacterium*”), *C. pseudogenitalium*, *C. segmentosum*, *C. thermoaminogenes* and *C. tuberculostearicum*.

The core description of the genus *Corynebacterium* has been emended substantively over the years, on the basis of comprehensive 16S rRNA gene sequence analysis for taxa with specific chemotaxonomic, morphological and phenotypic traits. These traits include: 1) the G+C content, which varies from 46 mol% (*C. kutscheri*) to 74 mol% (*C. auris*) (Funke et al., 1995b), but generally ranges from 51 to 65 mol%, indicating wide diversity within this genus (Collins and Cummins, 1986); 2) the cell wall, which contains meso-diaminopimelic acid (*m*-DAPA) as the diamino acid; and 3) short-chain mycolic acids called “corynemycolates” with 22–36 carbon atoms (Collins and Cummins, 1986) in all validly described species except *C. amycolatum* (Collins et al., 1988) and *C. kroppenstedtii* (Collins et al., 1998). Degradation products of corynemycolates, if present in abundance, may be observed to co-elute with cellular fatty acids (CFAs) of *Corynebacterium* species when analyzed using the Sherlock system (MIDI, Newark, DE; Bernard et al., 1991; Funke et al., 1995a). The cell wall of *Corynebacterium* species also contains arabinose and galactose (arabinogalactan; Collins and Cummins, 1986); 4) straight-chained saturated and unsaturated CFAs with significant volumes of palmitic (C16:0), oleic (C18:1 ω 9c) and stearic (C18:0) acids as the main CFAs. Tuberculostearic acid (C10 Me18:0) may be found in small volumes in lipophilic species (Bernard et al., 1991; von Graevenitz et al., 1991) but also in some non-lipophilic ones such as *C. minutissimum* and *C. confusum*. A large volume of C16:1 ω 7c is found in *C. diphtheriae*, *C. ulcerans* and *C. pseudotuberculosis* but not in any other *Corynebacterium* species to date and so may be useful as a rapid identifier (Bernard et al., 1991); 5) dihydrogenated menaquinones

with eight and/or nine isoprene units (Collins and Cummins, 1986). Noncovalently bound lipids play a key role in the formation of the cell wall permeability barrier and fracture plane (Puech et al., 2001; see the chapter on Corynebacterium—Nonmedical in this Volume).

Gram staining of corynebacteria shows short or medium length, slightly curved, Gram-positive rods with non-parallel or “palisading” sides and widened ends, giving some organisms a club shape. However, some species differ from that classic morphology in demonstrating longer (*C. durum*) or thinner rods with “bulges” (*C. sundsvallense*) or “whiphandles” (*C. matruchotii*; see the section on Identification in this Chapter).

The genus *Corynebacterium* includes fermentative and oxidative species as well as species that neither ferment nor oxidize. All are catalase-positive, and medically relevant species are nonmotile. Twelve species or biovars to date are lipophilic, i.e., they grow poorly at 35–37°C in 24 h or longer on standard laboratory media but show enhanced growth in 48–72 h on sheep blood or brain heart infusion broth enriched with a lipid such as 0.1–1.0% Tween 80 (Riegel et al., 1994) or serum added to carbohydrate broth (Hollis and Weaver, 1981). Lipophilism has been

serendipitously observed in *C. accolens* when enhanced growth was observed in the presence of *Staphylococcus aureus*, which supplied exogenous enrichment (Neubauer et al., 1991).

Habitat

The medically important corynebacteria are commensals and/or pathogens in man and animals. As commensals, they can be found on the skin or on mucous membranes (see the sections on Ecology and Individual Species in this Chapter). Table 1 lists corynebacteria recovered from animals.

Isolation

Sampling for corynebacteria follows the usual procedures for medical bacteria. Special precautions are not necessary. Their maintenance is assured in the usual semi-solid transport media.

Although corynebacteria grow on the usual blood and chocolate agars (but not on enteric media) when incubated aerobically, growth of lipophilic species (Table 2) is strongly enhanced by the addition of 0.1–1% Tween 80 (Riegel

Symbols: +, positive; -, negative; V, variable; O, delayed or weak reaction; and ND, no data.

Abbreviations: PYZ, pyrazinamidase; PAL, alkaline phosphatase; CAMP reaction, Christie-Atkins-Munch-Petersen reaction; F, fermentative; O, oxidative; TBSA, tuberculoostearic acid; REV, CAMP inhibition reaction; PYRa, pyrrolidonyl arylamidase (using API Coryne, API ZYM [Biomertieux]) or equivalent; and unk, unknown.

^aPA detected, propionic acid detected as a glucose fermentation product.

^b*C. bovis* blood culture isolate was also ONPG positive, oxidase positive, weakly maltose positive but negative by API Coryne; propionic acid was not detected; β -galactosidase was not observed using two methods (API Coryne and API Zym); API Coryne code obtained 0101104 (K. A. Bernard et al., 2002).

^c*C. diptheriae* biovar *mitis* is nitrate reductase + and *C. diptheriae* biovar *belfanti* is nitrate reductase -.

^d*C. mycetoides* originally recovered from human skin ulcer. The reference strain of this species (NCTC 9864 = ATCC 43995) has been the only strain recovered and cited in the literature since its validation in 1982. Data here are from Hollis and Weaver, 1981.

^e*C. simulans*, a strong nitrite reducer at low and high concentrations, may appear to be nitrate reduction negative unless further tested using zinc dust; one strain was catalase negative (Bernard et al., 2002).

^fShukla et al. (2001) found 1 strain to be pyrazinamidase and alkaline phosphatase positive but Bernard et al. (2002) found strains to be negative for these enzymes, using an API Coryne strip, giving rise to the code 0000125.

Bernard et al. (unpublished data).

et al., 1994; see the section on Phylogeny and Taxonomy). Nonfermentative species will show very limited growth under anaerobic conditions. Media (such as colistin-nalidixic acid blood agar) that are mostly inhibitory for Gram-negative bacteria may be used to select corynebacteria. Fosfomycin may also be added to blood agar either as a disk (Wirsing von König et al., 1988) or as fosfomycin-sodium succinate (100–200 mg + 12.5 mg of glucose-6-phosphate per liter; Hiramune et al., 1988; von Graevenitz et al., 1998c).

In addition, various selective media are available for *C. diphtheriae*, such as Tinsdale agar (Tinsdale, 1947), cystine-tellurite blood agar (Frobisher, 1937), Hoyle's lysed blood tellurite agar (Hoyle, 1941), and a liquid enrichment medium (Calalb et al., 1961). They are based on the ability of tellurium to inhibit most other bacteria except Gram-positive cocci, corynebacteria, and yeasts, which however produce smaller colonies on tellurite media than does *C. diphtheriae*. Furthermore, *C. diphtheriae* reduces tellurium salts to tellurium, which accumulates in the colonies, rendering them black. On Tinsdale agar, *C. diphtheriae* and the closely related species, *C. ulcerans* and *C. pseudotuberculosis*, also produce gray haloes due to the action of cystinase on L-cystine which yields hydrogen sulfide. Nonselective media for the isolation of *C. diphtheriae*, such as Loeffler's or Pai's slants (MacFaddin, 1985), favor its growth over other organisms and yield a characteristic microscopic and colonial morphology (see the section on *C. diphtheriae* in this Chapter).

For other corynebacteria (e.g., *C. jeikeium* and *C. urealyticum*), selective media based on "natural" resistance to certain antimicrobials have been devised as well, e.g., blood agar containing gentamicin (Tompkins et al., 1982), ticarcillin + fosfomycin + 5-fluorouracil (Wichmann et al., 1984) with cefotaxime added (De Briel et al., 1991), or polymyxin B + aztreonam + amphotericin B (Zapardiel et al., 1998) with fosfomycin added (Garcia-Bravo et al., 1997).

Detection of corynebacteria by polymerase chain reaction (PCR) methods will be covered in the discussion of individual species (see Individual Species).

Identification

Stains

Gram stains of corynebacteria from routine media reveal a typical coryneform morphology, i.e., of straight to slightly curved, nonsporeforming, non-acid-fast Gram-positive rods, often with tapered ends, sometimes club-shaped or ellipsoidal, arranged in angular or palisade formations

Fig. 1. Gram stain of a 24-h culture of *C. amycolatum* ATCC 49368 on sheep blood agar.

(Fig. 1; see the section on Phylogeny and Taxonomy). Staining may be uneven. These features may, however, be observed in any of the "coryneforms" (e.g., *Actinomyces* and *Arcanobacterium*) and have, therefore, little specificity for true corynebacteria. A few species have characteristic morphologies (e.g., *C. durum*, *C. sundsvallense*, *C. matruchotii*; see the section on Individual Species in this Chapter). When a special stain (e.g., Loeffler's methylene blue; MacFaddin, 1985) on *C. diphtheriae* growing on Loeffler's or Pai's slants is applied, characteristic slender rods in V- or L-shaped arrangements are seen, with metachromatic (polyphosphate) granules at one or both ends or in the center that appear reddish within the blue cells. When Neisser's stain (MacFaddin, 1985) is used, metachromatic granules will stain brownish-black, and the cells stain yellow. On other media and in other corynebacterial species (e.g., *C. pseudodiphtheriticum* and *C. imitans*), metachromatic granules are poorly, if ever, seen.

Culture Media

Colonial morphologies of corynebacteria are not characteristic except: 1) lipophilic species form very small colonies on unsupplemented blood or chocolate agar, and 2) *C. amycolatum*, *C. xerosis* and *C. matruchotii* show mainly rough colony types. Biovars of *C. diphtheriae* may be distinguishable on cystine-tellurite blood agar, with biovar *gravis* (and *C. ulcerans*) showing large gray to black colonies with a granular, radially striated surface and crenated margins and biovar *mitis* showing intensely black colonies with a glossy convex surface and regular margins (see the section on *C. diphtheriae* in this Chapter). This biovar may also cause a slight β -hemolysis. The rare biovar *intermedius* is lipophilic. A presumptive diagnosis of *C. diphtheriae* may also be

made from colonial morphology on Tinsdale agar (see the section on Isolation in this Chapter).

Biochemical Reactions

Corynebacteria cannot be speciated in the clinical laboratory without testing for biochemical reactions. While all are catalase-positive, individual species either do or do not ferment carbohydrates (which can be assessed on triple sugar iron agar or Kligler's agar). Further indispensable reactions are those for lipophilism, nitrate reduction, urease production, esculin hydrolysis, acid production from various sugars (at least from glucose, maltose, sucrose, xylose and mannitol), and the CAMP (Christie-Atkins-Munch-Petersen) reaction, which tests synergistic hemolysis with a β -hemolysin-producing strain of *S. aureus* (von Graevenitz and Funke, 1996). One may also include pyrazinamidase and alkaline phosphatase (von Graevenitz et al., 1998a), susceptibility to the vibriostatic agent O/129, growth at 20°C, nitrite reduction, fermentation of glucose at 42°C, as well as other hydrolytic, fermentation, and assimilation reactions (Renaud et al., 1996; Früh et al., 1998; Hommez et al., 1999; Wattiau et al., 2000).

Miniaturized systems for identification are available as well, such as API (RAPID) Coryne (API bioMérieux, La Balme-les Grottes, France), which is based on pre-formed enzyme reactions and acid formation from sugars. Its second version correctly identified, after 24 h, 93.5% of the corynebacterial species included in the database; however, in 64%, additional tests were necessary, mainly to differentiate *C. amycolatum* from *C. striatum* (Funke et al., 1997e). The Biolog system (Biolog, Hazelwood, CA, United States), based on utilization reactions, correctly identified (in 24 h) 38% of corynebacterial strains to species and an additional 29% to genus level only (Lindenmann et al., 1995). Fifty-four percent of *C. bovis* strains were correctly identified with this system (Watts et al., 2000). The RapID CB Plus system (bioMérieux), based on utilization and single substrate enzymatic tests, correctly identified 81.2% of corynebacterial strains to species and an additional 7.2% to genus level in 24 h (Funke et al., 1998d).

Chemotaxonomic Tests

In some instances, chemotaxonomic tests may be necessary to differentiate corynebacteria from other genera. Among them, cellular fatty acid analysis (Bernard et al., 1991; von Graevenitz et al., 1991) and determination of metabolic fatty acids (Reddy and Kao, 1978; Früh et al., 1998; Bernard et al., 2002) are particularly valuable.

Patterns of the former are almost genus-specific (see the section on Phylogeny and Taxonomy in this Chapter). Metabolic acids are not species-specific, but certain acids are only observed in certain species (e.g., propionic acid in *C. diphtheriae*, *C. ulcerans*, *C. amycolatum* and *C. glucuronolyticum* and succinic acid in these species as well as in *C. minutissimum*, *C. pseudotuberculosis*, *C. renale*, *C. striatum* and CDC Group G; Frueh et al., 1998; Table 2). Patterns of corynemycolic acid as obtained by high pressure liquid chromatography have been found specific for five species (De Briel et al., 1992), but routine diagnostic use of corynemycolic acid patterns has not been investigated or recommended. Recently, Fourier-transform infrared spectroscopy has been used for identification, with >87.3% correct results at the species level (Oberreuter et al., 2002).

Molecular Tests and Typing

16S rRNA gene sequencing is now widely used for speciation. In one study, the MicroSeq 500 16S bacterial sequencing kit (Perkin-Elmer Biosystems, Foster City, CA, United States) which sequences the 527-bp 5' end of the 16S rRNA gene gave results for the genus concordant with phenotypic tests in all of 42 isolates but was correct for species only in 64.3% of strains (Tang et al., 2000).

Amplified rDNA restriction analysis (ARDRA) with the enzymes *Alu* I, *Cfo* I and *Rsa* I was able to separate most corynebacterial species except a few non fermentative ones (Vanechoutte et al., 1995). Ribotyping using various restriction enzymes has been applied successfully to identification of corynebacterial species (Riegel et al., 1993a; Riegel et al., 1993b; Björkroth et al., 1999), as has analysis of the 16S–23S rRNA intragenic spacer region in single species (Aubel et al., 1997), pulsed field gel electrophoresis (PFGE; Connor et al., 2000), and whole-cell protein profiling (Sjöden et al., 1998), although gel-to-gel variation may be considerable.

For strain typing, amplified fragment length polymorphism (AFLP; De Zoysa and Efstratiou, 2000) has been seen as an alternative to ribotyping (Gruner et al., 1992). Although it could not distinguish three ribotypes of *C. diphtheriae*, it was able to discriminate three other ribotypes further. Other methods used for typing this species are PFGE (De Zoysa et al., 1995) and random amplification of polymorphic DNA (RAPD) (De Zoysa and Efstratiou, 1999), multilocus enzyme electrophoresis (MEE), and single strain conformation polymorphism (SSCP; Popovic et al., 1999). Ribotyping, however, is considered the standard for *C. diphtheriae* by the

European Laboratory Working Group on Diphtheria (Popovic et al., 2000). Molecular typing methods, mostly ribotyping, have also been used to differentiate between isolates of *C. jeikeium* and *C. urealyticum* (Soto et al., 1991; see the section on Epidemiology in this Chapter).

Preservation

Well-grown cultures of corynebacteria may be kept on Loeffler's, Pai's, or blood agar slants at room temperature for months to years (Mitscherlich and Marth, 1984). Alternatively, they may be lyophilized in the usual manner.

Physiology

Toxins

Exotoxins may be formed by strains of *C. diphtheriae*, *C. ulcerans* and *C. pseudotuberculosis* and are recognized virulence factors. A review of the diphtheria toxin (DT) and its formation has appeared recently (Holmes, 2000). Target organs are the heart (myocardium) and nerve tissues.

The DT (a 58-kDa protein with 535 amino acids) consists of three domains of known sequence: 1) the N-terminal C domain, responsible for adenosine diphosphate (ADP) ribosylation of elongation factor (EF)-2; 2) the central T domain, responsible for insertion into membranes at an acidic pH, channel formation, and translocation of the C domain across the endosomal membrane into the cytosol; and 3) the C-terminal R domain, responsible for binding of DT to the receptor, i.e., the heparin-binding epidermal growth factor (HB-EGF) precursor on susceptible cells. Proteolytic "nicking" results in fragments A (corresponding to the C domain) and B (corresponding to the T and R domains), which however remain connected by a single disulfide bond. Binding is followed by receptor-mediated endocytosis of DT. The acidic pH induces a conformational change and allows the central domain to be inserted into membranes and to form a channel through which translocation of the A fragment occurs across the endosomal membrane into the cytosol. The A fragment, having become enzymatically active following reduction of the disulfide bond, catalyzes the transfer of ADP-ribose from nicotinamide adenine dinucleotide (NAD) to EF-2, thus inactivating the latter and thereby inhibiting protein synthesis (chain elongation on the ribosome). The acceptor for the ribosylation is diphthamide, a post-translationally modified histidine.

The DT inhibits protein synthesis in cell-free extracts from all animal species but is toxic to

intact cells of certain mammals only, probably because of the presence of high-affinity receptors. It is synthesized by strains that are lysogenic for the bacteriophage β , which carries the structural gene *tox*. Thus, toxigenicity is determined by lysogenic conversion, and the *tox* determinant of corynebacteriophage β is the structural gene for DT.

Nontoxigenic strains either do not have detectable *tox*-related sequences or have such sequences that (probably as a result of a point mutation) do not encode functional DT. Also, rare strains with no infective corynebacteriophages have been observed (Cianciotto and Groman, 1997). The virulence of such strains to date has not been explained. All *tox*-bearing corynebacteriophages (except the δ phage), including the mutant ones, share extensive homology and have similar restriction fragment length polymorphism (RFLP) patterns with the β -converting phage (Buck et al., 1985). Chromosomal integration occurs in analogy to λ lysogenization of *Escherichia coli* (Buck and Groman, 1981). Two sites (*attB* 1 and *attB* 2), located on the bacterium, serve to attach the β -prophage with its attachment site *attP* on the chromosome. The *tox* gene is located adjacent to this site.

Addition of iron to growth media for *C. diphtheriae* inhibits toxin production (Pappenheimer and Johnson, 1936) owing to the diphtheria toxin repressor DtxR, a 226-amino-acid polypeptide encoded by *dtxR* and acting at the level of transcription of the DT gene. DtxR binds DNA by a sequence-specific mechanism and functions as an iron-dependent regulatory protein that represses DT synthesis, corynebacterial siderophore, and other components of iron uptake. A possible utilization of heme or hemoglobin as iron source is regulated by the *hmuO* gene (Schmitt, 1997). Specific recombination between *attP* and the *attB* attachment sites may also occur in *C. ulcerans* and *C. pseudotuberculosis*, which will then produce DT. Other corynebacterial species, even though they may show *attB*-related sequences (Cianciotto et al., 1986), have never been observed to produce DT.

The traditional test for the detection of DT uses two guinea pigs, both of them injected intraperitoneally with a broth culture of the bacterium, but only one of them protected by antitoxin. Toxigenic strains will cause death in the unprotected animal within 1–3 days, with characteristically swollen and hemorrhagic adrenal glands upon autopsy. This test has now been replaced by a variety of in vitro methods, which have recently been reviewed (Efstratiou et al., 2000). The widely used immunoprecipitation (Elek) test (Elek, 1949) has recently been modified in various ways (Engler et al., 1997; Reinhardt et al., 1998) to overcome its dependency on the quality of the reagents and the time needed for completion.

PCR amplification of a 246-bp fragment of the DT gene (Pallen, 1991; Mikhailovich et al., 1995) has also found acceptance but only detects DT gene sequences of both fragments, not active DT itself, and as such would not be a determinative test. New immunological tests such as enzyme immunoassay (EIA; Engler and Efstratiou, 2000), immunoblotting (Hallas et al., 1990), ADP ribosylation of EF-2 (Hauser et al., 1993), and immunochromatography (Engler et al., 2002) only detect fragment A but have at least a shorter time frame than the Elek test. The Vero cell bioassay (Miyamura et al., 1974) is specific for active DT but requires specialized tissue culture facilities and more time than the other tests. Concordance between the in vivo, cytotoxicity and modified Elek tests has been found very high, i.e., over 99% (Efstratiou et al., 1998).

A second toxin found only in *C. ulcerans* and *C. pseudotuberculosis* is phospholipase D (PLD), which hydrolyzes sphingomyelin in mammalian cell membranes, thereby releasing choline (Soucek et al., 1971). The genes and gene products of the two species show 80% DNA sequence homology and 87% amino acid sequence homology, respectively (Cuevas and Songer, 1993), and their PLD has more than 60% DNA and amino acid sequence homology with the PLD of *Arcanobacterium haemolyticum* (McNamara et al., 1995). PLD can be detected by inhibition of the CAMP test.

Other Potential Virulence Factors

Potential adhesins such as hemagglutinins, hydrophobins, sugar residues, and enzymes with *trans*-sialidase activity have been described in *C. diphtheriae* (Mattos-Guaraldi et al., 2000). Extracellular slime production was found in central nervous system shunts colonized by *C. jeikeium*, *C. amycolatum* and nonspeci-ated corynebacteria (Bayston et al., 1994). In *C. urealyticum*, however, adherence does not seem to be a predictor for virulence (Marty et al., 1991).

Plasmids

Plasmids have thus far been found in *C. renale* (Nath and Deb, 1995), *C. diphtheriae* and *C. jeikeium*. In six epidemic erythromycin- and clindamycin-resistant strains of *C. diphtheriae*, a single plasmid of 9.6 MDa was detected containing the *ermCd* gene, which encoded an inducible rRNA methylase (Roberts et al., 1992). In a study of 39 "JK type" corynebacteria, 23 possessed plasmids, forming six groups on restriction endonuclease analysis. Four groups with a plasmid DNA of over 6.4 kbp were associated with a bacteriocin-like substance but not with antimicrobial resistance (Kerry-Williams and

Noble, 1986; Pitcher et al., 1990). Sequencing of the multiresistance plasmid pTP10 from a strain of *C. striatum* has provided genetic information on the mechanisms of resistance to 16 antimicrobials (Tauch et al., 2000).

Ecology

Medically important corynebacteria are commensals and potential pathogens in man and animals. Some data are available on their survival in the inanimate environment, as well as on the species distribution in the normal flora.

Corynebacterium diphtheriae strains from carriers may be toxigenic or nontoxigenic and may be found in the throat, in the nose, or on the skin (see the section on *C. diphtheriae* in this Chapter). While carriage in the upper respiratory tract is now rare among healthy populations in non-epidemic areas, it may become prevalent during epidemics of throat diphtheria (Mikhailovich et al., 1995). Skin carriage, mostly of nontoxigenic strains, is in the United States and Western Europe nowadays associated with homelessness and intravenous drug abuse but has been recently discovered in other populations as well (Funke et al., 1999a; see the section on *C. diphtheriae*). The organism is also able to survive in the inanimate environment of patients with diphtheria, albeit rarely (Larsson et al., 1987), and has survived in milk as well (Kersten, 1909).

On healthy skin, *C. jeikeium* has been detected in intertriginous areas (Larson et al., 1986a; Larson et al., 1986b), and large-colony diphtheroids as well as unspecified lipophilic diphtheroids were found on the same sites, in the anterior nares, and in the axilla (Aly and Maybach, 1977). There was an inverse correlation between the occurrence of these lipophilic strains and of *C. jeikeium* in healthy as well as diseased individuals, but the frequency and density of *C. jeikeium* in diseased individuals were higher (Larson et al., 1986b). This organism is also able to survive in the inanimate environments such as air and surfaces in the rooms of patients (Quinn et al., 1984; Telander et al., 1988). The same is true for *C. urealyticum* (Nieto et al., 1996), which may also be isolated from the intact skin of hospitalized patients (Soriano et al., 1988), and for *C. striatum* (Brandenburg et al., 1996). *Corynebacterium minutissimum* may also be part of the normal skin flora (Pitcher, 1978).

Corynebacteria belonging to the normal flora of mucous membranes have only been speciated recently (Funke et al., 1997f; Gordts et al., 2000). In one study of throat cultures of two different populations, *C. durum* was found as the most frequent corynebacterium, followed by CDC Group G, *C. jeikeium* and *C. pseudodiphtheriti-*

cum (von Graevenitz et al., 1998c). The normal conjunctival flora, on the other hand, contains only lipophilic corynebacteria; in one series, they were CDC Group G, *C. macginleyi*, *C. afermentans* subsp. *lipophilum*, *C. accolens* and *C. jeikeium* (von Graevenitz et al., 2001).

Of the veterinary corynebacteria, *C. renale*, *C. pilosum* and *C. cystitidis* are able to survive in soil (Hayashi et al., 1985).

Epidemiology

Except for *C. diphtheriae*, little is known about the spread of corynebacteria. Diphtheria bacilli are known to spread via droplets from the respiratory tract. In the Western hemisphere, however, spread is often from skin lesions via contact or injection paraphernalia (Gruner et al., 1994; see the section on *C. diphtheriae*). Occurrence of a clone of nontoxigenic isolates, first reported from Switzerland (Gruner et al., 1992), was later reported from Northern Germany as well (Funke et al., 1999a). Skin transmission, in fact, seems to be more efficient than throat transmission (MacGregor, 2000). Epidemic transmission from milk, reported in the early literature (Henry, 1920), seems to have been due to milkers' hand contamination and has not been reported lately. Molecular typing of *C. jeikeium* (Kerry-Williams and Noble, 1986; Khabbaz et al., 1986; Pitcher et al., 1990) and of *C. urealyticum* (Soto et al., 1991) has yielded conflicting evidence as to whether patient-to-patient transmission occurred. Such spread has been documented for *C. striatum*, however (Leonard et al., 1994; Brandenburg et al., 1996).

Individual Species

With some exceptions (such as *C. diphtheriae* and closely related taxa), corynebacteria appear to be infrequent human pathogens. Taxonomy and disease potential of these bacteria have so far only sporadically been investigated and thus are still only partially understood. Some species isolated from humans are represented in the literature by only a single strain or a small number of strains and thus lack sufficient depths to demonstrate a possible heterogeneity of phenotypic reactions, which is a less than ideal situation (Christensen et al., 2001). A comprehensive review of medically relevant coryneforms, including a description of older/provisional taxonomic designations, was published in 1997 (Funke et al., 1997f); this background will not be reiterated here. The species are presented in alphabetical order. Colony description is based on at least 24-h growth at 35–37°C on 5% sheep

blood agar. Biochemical reactions commonly used for identification are listed in Table 2. Additional tests, including chemotaxonomic and molecular genetic studies, may be required in a few instances.

Corynebacterium accolens

Corynebacterium accolens is a lipophilic *Corynebacterium* species recovered from eye specimens, including from the healthy human conjunctiva (von Graevenitz et al., 2001), ears, nose, and the oropharynx (Neubauer et al., 1991). Native aortic and mitral valve endocarditis due to this agent has been described (Claeys et al., 1996). *Corynebacterium accolens* resembles phenotypically CDC group G, except for certain enzyme reactions. Strains to date have been susceptible to a broad spectrum of antibiotics, whereas CDC group G is often multiresistant (Funke et al., 1996b).

Corynebacterium afermentans

Corynebacterium afermentans consists of two subspecies found to be relatively nonreactive in substrates, *C. afermentans* subsp. *afermentans* and *C. afermentans* subsp. *lipophilum* (Table 2), and to have a nonfermentative metabolism (Riegel et al., 1993b). Both subspecies may demonstrate a positive CAMP reaction.

Corynebacterium afermentans subsp. *afermentans* is part of normal human skin flora and has been isolated mainly from blood cultures (Riegel et al., 1993b). Sepsis in a neurological patient has been reported (Kumari et al., 1997). *Corynebacterium afermentans* subsp. *afermentans* is difficult to differentiate from *C. auris* and *Turicella otitidis* solely by phenotypic means and even by a larger set of substrates such as that found in the Biolog (Biolog, Inc., Hayward, CA) or other assimilation systems (Funke et al., 1994; Renaud et al., 1996). These taxa may be differentiated by 16S rRNA gene sequencing and chemotaxonomically, as both *C. afermentans* and *C. auris* contain corynemycolates, but *T. otitidis* does not.

Corynebacterium afermentans subsp. *lipophilum* has been isolated from blood cultures as well as from superficial wounds (Riegel et al., 1993a) but may also be recovered from the healthy conjunctiva (von Graevenitz et al., 2001). It has been reported to be an agent of severe disease, including prosthetic valve endocarditis (Sewell et al., 1995) and disseminated infection associated with abscess formation (Dykhuizen et al., 1995). As the name suggests, this is a lipophilic species with smooth, rounded colonies <0.5 mm in diameter after 24 h of incubation. *Corynebacterium afermentans* subsp. *lipophilum* grows poorly on non-lipid containing media when compared to other

phenotypically nonreactive taxa that grow luxuriantly in 24 h (*C. auris*, *C. afermentans* subsp. *afermentans* and *T. otitidis*), which assists with identification.

Corynebacterium amycolatum

This species was originally recovered as a commensal from normal human skin flora (Collins et al., 1988), but its role in human disease was not further elucidated until the mid-1990's. It is acknowledged to be the most frequently encountered *Corynebacterium* species derived from human clinical material (Funke et al., 1997f). Recent reports have attributed a role in fatal sepsis in a premature infant (Berner et al., 1997), a cardioverter-lead electrode infection (Vanechoutte et al., 1998), septic arthritis (Clarke et al., 1999), catheter-related infection, surgical wound infection, pilonidal cyst formation (Esteban et al., 1999), sepsis in neutropenic patients (de Miguel et al., 1999), bacteremia (Oteo et al., 2001), and native valve endocarditis (Knox and Holmes, 2002). *Corynebacterium amycolatum* strains are usually multidrug resistant (de Miguel-Martinez et al., 1996; Funke et al., 1996b; Lagrou et al., 1998; Troxler et al., 2001; Knox and Holmes, 2002). This species has not been recovered from throat swabs of healthy individuals (von Graevenitz et al., 1998a). *Corynebacterium amycolatum* is one of two corynebacterial species lacking corynemycolates in its cell wall (Collins et al., 1988), is metabolically fermentative and is very diverse in its reaction to standard phenotypic tests, which has been the basis for misidentification as *C. xerosis*, *C. striatum* or *C. minutissimum* (Zinkernagel et al., 1996; Wauters et al., 1998). Gram stain of this bacterium is shown in Fig. 1. All *C. amycolatum* strains produce propionic acid as major end product of glucose metabolism. Acyl phosphatidylglycerol is a major phospholipid in *C. amycolatum* in contrast to other *Corynebacterium* spp., in which other phospholipids are predominant (Collins et al., 1988).

Corynebacterium appendicis

This species was recently described on the basis of a single strain recovered from an abdominal swab of a patient with appendicitis and abscess formation. It is a urease-positive, lipophilic *Corynebacterium* species that slowly ferments glucose and maltose (Yassin et al., 2002a; Table 2).

Corynebacterium argenteratense

On the basis of phylogenetic studies, this species is closest to *C. diphtheriae* and the related species

C. ulcerans and *C. pseudotuberculosis*, but lacks the diphtheria *tox* gene (Riegel et al., 1995a). To date, *C. argenteratense* has been isolated from the human throat (Riegel et al., 1995a; von Graevenitz et al., 1998c) as well as from a blood culture (Bernard et al., 2002). The CAMP-negative *C. argenteratense* phenotypically resembles *C. coyleae* strains, which are CAMP positive (Table 2). Like *C. diphtheriae* and closely related species, *C. argenteratense* produces propionic acid as a product of glucose fermentation (Bernard et al., 2002). *Corynebacterium argenteratense* is the only medically relevant *Corynebacterium* species that exhibits α -chymotrypsin in the API Zym (bioMérieux) system; however, a blood culture isolate was not observed to produce that enzyme (Bernard et al., 2002).

Corynebacterium aurimucosum

This species has been recently proposed for two strains, one recovered from a human blood culture (Yassin et al., 2002b). As a unique characteristic on sheep blood agar plates, it has, after a 24-h incubation, colonies that are yellowish, sticky and about 1–2 mm in diameter, but on trypticase soy agar without blood supplement, it lacks pigment and is described as slimy. Phenotypically, this species is most similar to *C. minutissimum* except for a lack of alkaline phosphatase activity.

Corynebacterium auris

This species was originally recovered from the ears of pediatric patients with ear infections (Funke et al., 1995b). On the basis of colonial, chemotaxonomic, and genetic studies, *C. auris* strains were found to be discernible from other minimally reactive taxa (e.g., *C. afermentans* subsp. *afermentans* and *Turicella otitidis*; Funke et al., 1994; Funke et al., 1995b), which they otherwise closely resemble phenotypically (Table 2). *Corynebacterium auris* strains are CAMP test positive. Increased minimum inhibitory concentrations (MICs) for β -lactam antibiotics in *C. auris* strains have been observed, but the mechanism is unknown (Funke et al., 1996b).

Corynebacterium bovis

One case study exists that implicates the lipophilic *Corynebacterium* species *C. bovis* as a rare causative agent of human disease (Vale and Scott, 1977), but otherwise this species is an agent of bovine mastitis, a significant disease in cattle (Watts et al., 2000). Human isolates would now presumably have been assigned to one of a number of other lipophilic *Corynebacterium* species if polyphasic methods and recent identifica-

tion schemes had been available. In a 1997 review, it was mentioned that in fact this species had not been definitively recovered for many years from human clinical material (Funke et al., 1997f). Recently, however, a human blood culture isolate of *C. bovis* was identified on the basis of a polyphasic approach, including phenotypic, chemotaxonomic and genotypic characteristics (Bernard et al., 2002). Microbiologists should therefore be cognizant of the possibility that this bovine disease agent may on rare occasions be recovered from human specimens.

Corynebacterium confusum

This species has been isolated from patients with foot infections, a clinical blood sample (Funke et al., 1998b), and from a breast abscess (CAMP positive isolate; Bernard et al., 2002). *Corynebacterium confusum* reduces nitrate but characteristically will only slowly and weakly ferment glucose and is poorly reactive in most substrates. A small volume of tuberculostearic acid (TBSA) is observed on CFA analysis. This species may require additional testing such as for tyrosine hydrolysis and CAMP reaction to separate it from *C. argentoratense*, *C. coyleae* (which is CAMP positive) and *C. propinquum* (Table 2).

Corynebacterium coyleae

This species has been primarily isolated from normally sterile body fluids including blood cultures from patients with fever of unknown origin (postsurgically or in HIV infections), as well as from genitourinary specimens (Funke et al., 1997d; Bernard et al., 2002). Characteristically, it is CAMP positive and slowly ferments glucose and ribose, but few other sugars (Table 2).

Corynebacterium diphtheriae

Classical respiratory diphtheria, caused by toxigenic strains of *C. diphtheriae* or, rarely, by the closely related species *C. ulcerans*, was one of the most common causes of death among children in the pre-vaccine era (Golaz et al., 2001). Symptoms include a sore throat, low-grade fever, swelling of the neck, and a membrane on the tonsils or throat, which can be associated with asphyxiation if breathing is obstructed. Use of toxoid vaccine has virtually eliminated diphtheria in developed countries and significantly reduced it in developing countries (Golaz et al., 2001). Cutaneous infections are the second classically recognized DT-induced manifestation. An extensive outbreak of diphtheria in Russia and in newly independent states of the former Soviet Union was directly attributed to 1) declining immunity among adults who had received all or

most childhood immunizations but missed having booster shots, 2) persistence of circulating *C. diphtheriae* strains in the population, and 3) dramatic socioeconomic changes (Efstratiou and George, 1996; Popovic et al., 2000). Only a massive immunization program of 70 million people halted the outbreak (Golaz et al., 2000). Developing countries continue to be at considerable risk (Gilbert, 1997), but waning immunity among populations in developed countries have put those people at risk as well, especially when traveling to countries lacking a universal immunization program (Marston et al., 2001).

A growing body of reports continues to document the emergence of newly recognized manifestations of *C. diphtheriae* disease in countries where it had been thought to be eradicated or substantively diminished. Serious diseases caused by nontoxigenic *C. diphtheriae* and closely related species, including splenic abscesses, bacteremia, septic arthritis, and endocarditis (Tiley et al., 1993; Gruner et al., 1994; Efstratiou and George, 1996; Hogg et al., 1996; Funke et al., 1999a; Belko et al., 2000) have been described (see the section on Epidemiology in this Chapter). Pharyngitis has been reported in homosexual, institutional, and military populations (Wilson, 1995; Gilbert, 1997; Reacher et al., 2000). Increased risk for significant infection exists for homeless (Harnisch et al., 1989), intravenous drug abusers (Gruner et al., 1994), and aboriginal populations (Hogg et al., 1996).

Corynebacterium diphtheriae is divided into four biovars—*gravis*, *mitis*, *belfanti* and *intermedius* (see Identification). Biovar differentiation is recommended (Efstratiou and George, 1999; Efstratiou et al., 2000), although biovars cannot be assigned subspecies status nor is their determination a relevant epidemiologic tracking method (Riegel et al., 1995d). Originally, biovars were defined by differences in colony morphology and biochemical tests. However, only the lipophilic biovar *intermedius* may be identified on the basis of colonial morphology (Coyle et al., 1993b). Other *C. diphtheriae* biotypes produce indistinguishable, larger white or opaque colonies after 24 h on sheep blood agar. Biovar *intermedius* occurs only rarely in clinical infections, and *C. diphtheriae* biovar *belfanti* strains rarely harbor the diphtheria toxin gene.

Biochemically, *C. diphtheriae* as well as closely related species, *C. pseudotuberculosis* and *C. ulcerans*, produces cystinase (detected by using Tinsdale medium or equivalent media) and lacks pyrazinamidase (Efstratiou and George, 1999; Efstratiou et al., 2000) and, by these tests, may be discerned from other species (Table 2). Propionic acid is produced as an end product of glucose metabolism (Estrangin et al., 1987; Fröh et al., 1998). *Corynebacterium diphtheriae* strains

differ from all other coryneform bacteria (except *C. pseudotuberculosis* and *C. ulcerans*) in their CFA patterns by the presence of a large volume of C16:1 ω 7c (Bernard et al., 1991).

Corynebacterium durum

First recovered from respiratory tract specimens, this species has been further isolated from the gingiva, blood cultures, and abscesses (Riegel et al., 1997a; Rassouliau-Barrett et al., 2001). This is the most frequent *Corynebacterium* species isolated from throat swabs of healthy persons (von Graevenitz et al., 1998c). Gram staining of aerobic cultures shows long and filamentous rods with occasional “bulges” but not *C. matruchotii*-like “whiphandles.” Differentiation between these two species may be difficult (Table 2), and in the past, some *C. durum* strains were almost assuredly misidentified as *C. matruchotii* when solely phenotypic methods were used (Hollis and Weaver, 1981). *Corynebacterium matruchotii* produces pyrrolidonyl arylamidase, whereas *C. durum* does not (Rassouliau-Barrett et al., 2001). Most *C. durum* strains hydrolyze esculin and ferment mannitol, which is otherwise unusual among *Corynebacterium* spp. (Rassouliau-Barrett et al., 2001). Both *C. matruchotii* and *C. durum* produce propionic acid as a fermentation product (Bernard et al., 2002).

Corynebacterium falsenii

Isolates have been recovered to date from blood culture and cerebral spinal fluid (Sjöden et al., 1998; Bernard et al., 2002). The original description of this species suggested that colonies after a 24-h incubation are whitish, smooth and glistening with entire edges, but with time (72–120 h), exhibit a yellowish pigment that increases in intensity. This phenomenon has otherwise only been rarely observed among *Corynebacterium* species. This species demonstrates a weak urease reaction, with other distinguishing features described in Table 2.

Corynebacterium freneyi

Isolates of this recently described species were derived from pus from a toe, varicose ulcers, and a subcutaneous abscess fistula (Renaud et al., 2001). Biochemically, these strains were nearly indistinguishable from *C. xerosis* and also similar to *C. amycolatum*. Both *C. xerosis* and *C. freneyi* produce α -glucosidase (Table 2). The two species, although closely related phylogenetically by 16S rRNA gene sequencing, could otherwise be differentiated by less commonly used biochemical tests, by 16S–23S intergenic spacer region analysis, and by DNA-DNA hybridization.

Corynebacterium glucuronolyticum

This species was originally recovered from male urogenital specimens but has also been recovered from blood cultures, peritoneal fluid, and dialysis fluid (Funke et al., 1995a; Bernard et al., 2002). *Corynebacterium seminale* (Riegel et al., 1995b) is a junior synonym of *C. glucuronolyticum* (Devriese et al., 2000). This species is the only medical *Corynebacterium* species that produces β -glucuronidase as well as reacts positively in a wide variety of biochemical tests. Urease, if produced, is abundant and its detection is rapid (<10 min; Table 2). Reactions for strains recovered from animals may differ from those recovered from diseased humans (Devriese et al., 2000). These bacteria may exhibit resistance to tetracycline, macrolides and lincosamides (Funke et al., 1996b). Culture-negative prostatic fluids were found to contain 16S rRNA gene sequences homologous with sequences derived for *C. glucuronolyticum*, suggesting that this agent may play a role in prostatitis (Tanner et al., 1999).

Corynebacterium imitans

Person-to-person transmission of this species was suggested when the isolate originally from the throat of a seriously ill child suspected to be suffering from pharyngeal diphtheria appeared as well in three ill adult contacts (Funke et al., 1997a). These strains, upon initial recovery, were described as being “atypical *C. diphtheriae*” because they expressed a number of phenotypic reactions very similar to those found for that species. Subsequent polyphasic analyses defined the group of isolates as a new species, *C. imitans* (Funke et al., 1997a; Table 2). Strains since recovered from blood cultures consistent genotypically and phenotypically with *C. imitans* did not produce propionic acid (unlike *C. diphtheriae*) and lacked the unique CFA composition associated with *C. diphtheriae* and closely related species (Bernard et al., 1991; Bernard et al., 2002). *Corynebacterium imitans* did not produce DT as assessed by the modified Elek test, by *tox* gene detection with PCR, and by use of an immunochromatographic strip (Funke et al., 1997a; Engler et al., 2002).

Corynebacterium jeikeium

This species, a lipophilic corynebacterium species associated with skin flora (Jackman et al., 1987), is one of the most frequently encountered *Corynebacterium* species in clinical specimens (Funke et al., 1997f; Lagrou et al., 1998). This bacterium can cause serious prosthetic joint infection (von Graevenitz et al., 1998b),

endocarditis (Jackman et al., 1987; Ross et al., 2001), bacteremia in bone marrow transplant patients with a Hickman catheter (Wang et al., 2001) and in neutropenic patients (Zinner et al., 1999), pneumonia and bacteremia associated with significant disease (Funke et al., 1997f), as well as otitis media (de Miguel-Martinez, 1999). Nosocomial transmission of this bacterium has been suggested (Pitcher et al., 1990). Most strains of *C. jeikeium* exhibit multiresistance to antibiotics but remain sensitive to vancomycin (Riegel et al., 1996; Lagrou et al., 1998). A novel glycopeptide, BI 397, exhibited significant activity against *C. jeikeium* in vitro (Jones et al., 2001). DNA-DNA hybridization studies have shown that *C. jeikeium* includes at least four genomospecies: two that are multiresistant and two that have low penicillin and gentamicin MICs but could not be differentiated phenotypically (Riegel et al., 1994). *Corynebacterium jeikeium* is phenotypically closest to CDC group G, but may be differentiated from that taxon by inability to grow anaerobically and to oxidize fructose (Riegel et al., 1994).

Corynebacterium kroppenstedtii,
C. lipophiloflavum and *C. macginleyi*

Corynebacterium kroppenstedtii was originally recovered from a sputum sample of a patient with pulmonary disease (Collins et al., 1998), with additional strains being isolated from a breast abscess, an open lung biopsy, as well as sputum (Bernard et al., 2002). It is a lipophilic corynebacterium, the second species in the genus to lack cell wall mycolates, and one of the few *Corynebacterium* species exhibiting esculin hydrolysis.

The description of *C. lipophiloflavum* is based on characteristics of one strain recovered from vaginal discharge from a patient with bacterial vaginosis (Funke et al., 1997b). That strain was found to exhibit an intensely yellow pigment, urease production, but relative substrate non-reactivity.

Corynebacterium macginleyi, initially described as isolates from ocular specimens (Riegel et al., 1995c), has since been recovered from diseased (Funke et al., 1998c; Jousen et al., 2000) as well as healthy eye specimens (von Graevenitz et al., 2001). These bacteria are lipophilic, with reactions as shown in Table 2.

Corynebacterium matruchotii

The association of this species, formerly *Bacterionema matruchotii* (Collins, 1982b), part of the flora of the oral cavity, with calculus and plaque deposits (Siqueira et al., 2000; Rassoul-Barrett et al., 2001) has been much studied but

otherwise recovery of this species from diseased humans has been rare. Gram-stained *Corynebacterium matruchotii* has a most remarkable appearance, which consists of “whips” of long filamentous bacteria with “whiphandles” formed from a short coccobacillus or bacillus attached to one end (Collins, 1982b). A polyphasic study of reference strains of this species has shown that they include some misidentified strains of *C. durum* (Rassoul-Barrett et al., 2001). One such *C. matruchotii* reference strain, ATCC 43833, has been shown to represent a novel species distinct from *C. matruchotii* and from *C. durum* (Rassoul-Barrett et al., 2001).

Corynebacterium minutissimum

This species is part of normal human skin flora and was originally thought to be the cause of erythrasma (Collins and Jones, 1983), but that premise has since been refuted (Coyle and Lipsky, 1990). This species recently has been recovered from patients with endophthalmitis (Arsan et al., 1995–1996) and peritonitis in a CAPD patient (Fernandez Giron et al., 1998). Readers are cautioned that antibiotic multiresistant or propionic acid-producing isolates identified as *C. minutissimum* are most likely *C. amycolatum* strains, if polyphasic identification approaches are used (Zinkernagel et al., 1996). Members of this species are usually DNase producers, hydrolyze tyrosine, are fermentative and, unlike most *Corynebacterium* species, are able to ferment mannitol (Zinkernagel et al., 1996; Table 2).

Corynebacterium mucifaciens

This species has been recovered from blood cultures and other sterile body fluids as well as from abscesses, soft tissues, and a CAPD dialysate (Funke et al., 1997c; Bernard et al., 2002). Its colonies are unusual and distinct among *Corynebacterium* species. They generally exhibit a slight to intense yellow or yellow-brown pigment and are mucoid, somewhat reminiscent of *Rhodococcus equi* colonies (see the chapter on The Phototrophic Alpha-Proteobacteria in Volume 5). The characteristic mucoid appearance was found by electron microscopy to be associated with discernible thin-to-thick cell-connecting filaments, assumed to be a polysaccharide and possibly related to virulence (Funke et al., 1997c). The mucoid appearance is less obvious after extended incubation for 96 h. One blood culture isolate, found to be closest to *C. mucifaciens* by polyphasic study including 16S rRNA gene sequence analysis, was aberrant in that it was not mucoid, not yellow pigmented and thus difficult to identify (Bernard et al., 2002). *Corynebacte-*

rium mucifaciens has an oxidative metabolism (Table 2) and may be separated from *R. equi* by Gram stain appearance, enzyme profile, biochemical reactions, and CFA composition (the TBSA volumes of *C. mucifaciens* being small, in contrast to the very large volumes found in *R. equi*). β -Lactam antibiotics and aminoglycosides show very good activities against *C. mucifaciens* (Funke et al., 1997c).

Corynebacterium mycetoides

This organism was originally isolated in 1942 from skin ulcers of soldiers in the desert of North Africa. The species was later validated (Collins, 1982a). To the best of our knowledge, clinical cases involving this agent have not to date been reported in the literature. Characteristics are shown in Table 2.

Corynebacterium propinquum

Corynebacterium propinquum is the name assigned to encompass the rare human pathogen CDC group ANF-3 (Hollis and Weaver, 1981; Riegel et al., 1993b). This species was thought to be the cause of a case of native valve endocarditis (Petit et al., 1994). It grows well in 24 h, but in biochemical tests other than nitrate reduction and tyrosine hydrolysis, it is relatively nonreactive (Riegel et al., 1993b).

Corynebacterium pseudodiphtheriticum

This species, part of the normal oropharyngeal flora in humans, in recent years has been documented to cause pneumonia in compromised and immunocompromised populations (Izurieta et al., 1997; Gutierrez-Rodero et al., 1999; Martaresche et al., 1999). One case of exudative pharyngitis with a pseudomembrane, which mimicked diphtherial pharyngitis, provoked a significant public health response (Izurieta et al., 1997). This agent has been recovered from keratitis and conjunctivitis (Li and Lal, 2000) and skin infection (Hemsley et al., 1999). Like *C. propinquum*, it is relatively nonreactive in most biochemical tests but does reduce nitrate and hydrolyze urea. *Corynebacterium pseudodiphtheriticum* strains are susceptible to β -lactam antibiotics, but resistance to macrolides and lincosamides has been observed (Gutierrez-Rodero et al., 1999).

Corynebacterium pseudotuberculosis

This species is primarily noted for causing caseous lymphadenitis in sheep, horses, and feral goats; however, it may on rare occasions cause lymphadenitis in humans who have occupational exposure to sheep (Peel et al., 1997). This species

is phylogenetically closely related to *C. diphtheriae* and *C. ulcerans* and, like those species, may harbor the diphtheria toxin gene (Pascual et al., 1995; Ruimy et al., 1995; Peel et al., 1997; see the section on Physiology in this Chapter). Like those species, the cell wall of *C. pseudotuberculosis* contains large amounts of the CFA, C16:1 ω 7c (Bernard et al., 1991). Like *C. ulcerans*, *C. pseudotuberculosis* produces urease and, like *Arcanobacterium haemolyticum*, is reverse CAMP positive (Hollis and Weaver, 1981). Molecular-level strain typing has been done using pulsed field gel electrophoresis (PFGE; Connor et al., 2000).

Corynebacterium riegelii

Strains of this species were originally recovered from urinary tract infections of human females (Funke et al., 1998a) but have also been isolated from blood cultures including cord blood (Bernard et al., 2002). *Corynebacterium riegelii* strains exhibit an unusual phenotypic characteristic of fermenting maltose but not glucose or most other sugar substrates. Urease, when present, is both rapidly and strongly positive (Funke et al., 1998a; Table 2).

Corynebacterium sanguinis, *C. simulans*, and *C. singulare*

These species have been recently described in the literature. Phenotypic reactions are represented by only a few strains.

Corynebacterium sanguinis has been recovered from blood culture isolates (G. Funke et al., submitted). Characteristically, this species slowly ferments glucose like *C. coyleae* but is CAMP negative. A small volume of TBSA (2–3%) was detected among CFAs.

Corynebacterium simulans was originally discerned from among some *C. striatum*-like isolates (Wattiau et al., 2000) and included isolates from a foot abscess, lymph node biopsy, and a boil. Two additional strains have been characterized from bile and an unusual, repeatedly catalase-negative isolate has been derived from blood culture (Bernard et al., 2002). *Corynebacterium simulans* is closely related phylogenetically to *C. minutissimum*, *C. singulare* and *C. striatum* and is the only species in the genus described to date that reduces nitrite.

Corynebacterium singulare has been recovered from semen and a blood culture (Riegel et al., 1997b). Its biochemical reactions were originally suggestive of *C. minutissimum*, including hydrolysis of tyrosine, except for urease positivity (Table 2). However, polyphasic identification, including phylogenetic analysis, found that these strains were closest to, but discernible from, *C.*

minutissimum. *Corynebacterium singulare* also does not produce propionic acid as a fermentation product from glucose (Riegel et al., 1997b).

Corynebacterium striatum

This species has been found to be part of the normal human skin flora but has been occasionally recovered from clinical samples in patients with endocarditis (Tattevin et al., 1996; Juurlink et al., 1996; Keijman et al., 2000), meningitis, septicemia, pneumonia, and other invasive infections (Martinez-Martinez et al., 1995; Martinez-Martinez et al., 1997; Weiss et al., 1996). Vertebral osteomyelitis due to this species has been reported (Fernandez-Ayala et al., 2001). Nosocomial transmission of *C. striatum* has been documented (Leonard et al., 1994; Brandenburg et al., 1996). *Corynebacterium striatum* strains hydrolyze tyrosine and are occasionally CAMP reaction positive. Resistance to macrolides and lincosamides due to the presence of an rRNA methylase has been described. *Corynebacterium striatum* may also be resistant to quinolones and tetracyclines (Martinez-Martinez et al., 1996).

Corynebacterium sundsvallense and *C. thomssenii*

Corynebacterium sundsvallense has been isolated from blood cultures, a vaginal swab, and fluid drained from an infected groin (Collins et al., 1999a). Gram staining shows bulges or knobs at the ends of some rods which may resemble those seen in *C. durum* or *C. matruchotii*, but biochemical methods may differentiate those species (Table 2).

Corynebacterium thomssenii was first repeatedly isolated from a patient with pleural effusion (Zimmermann et al., 1998). A second strain was recovered from an environmental specimen (Bernard et al., 2002). Characteristically, *C. thomssenii* is the only *Corynebacterium* species expressing *N*-acetyl- β -glucosaminidase activity. *Corynebacterium sundsvallense* and *C. thomssenii* are phylogenetically more closely related to each other than to all other *Corynebacterium* species and phenotypically most closely resemble each other (Bernard et al., 2002; Table 2).

Corynebacterium ulcerans

Phylogenetically, *C. ulcerans* is most closely related to *C. pseudotuberculosis* and to *C. diphtheriae* (Pascual et al., 1995; Riegel et al., 1995d; Ruimy et al., 1995). This includes the ability to harbor the diphtheria *tox* gene, to express diphtheria toxin, and to show the typical cell wall with significant amounts of C16:1 ω 7c (Bernard et al., 1991). Disease associated with this bacterium is

rare, but if recovered from pseudomembranous material, the disease must be treated as diphtheria (Funke et al., 1997f; Efstratiou and George, 1999; Efstratiou et al., 2000). Cutaneous diphtheria-like disease has been reported associated with *C. ulcerans* (Wagner et al., 2001). Biochemically, these bacteria are similar to *C. pseudotuberculosis*, including reactivity in the reverse CAMP test (Table 2).

Corynebacterium urealyticum

This species has primarily been recovered from urinary tract infections (UTIs) and is especially associated with UTI patient urine with an alkaline pH, resulting in struvite crystals (Funke et al., 1997f; Hertig et al., 2000). This bacterium has been recovered from patients with other serious illnesses including bacteremias associated with pyelonephritis, nephrolithiasis, cancer, and HIV infection (Fernandez-Natal et al., 2001), pericarditis (Ojeda-Vargas et al., 2000), and soft tissue infection (Saavedra et al., 1996). Most biochemical tests are negative except that for urease, which is strongly positive. A PCR-based assay for detection of *C. urealyticum* has been described (Simoons-Smit et al., 2000). Ribotyping has been used to characterize these strains (Nieto et al., 2000). *Corynebacterium urealyticum* is almost always multidrug resistant, but rare penicillin-susceptible strains have also been described (Funke et al., 1997f).

Corynebacterium xerosis

This species was once thought to be a commonly recovered *Corynebacterium* species from clinical material. However, most isolates described in case reports for *C. xerosis* prior to 1996 apparently were most likely misidentified *C. amycolatum* strains, and *C. xerosis* is actually a very rare human pathogen (Funke et al., 1996a). This difficulty in discerning *C. amycolatum* from *C. xerosis* was also found to extend to strains found in commercial culture collections (Coyle et al., 1993a). The newly described species *C. freneyi* is closely related to *C. xerosis* and must be carefully excluded when differentiating these taxa.

Coryneform CDC Group F-1, CDC Group G, and the "Black Pigmented" *Corynebacterium* species

CDC group F-1 bacteria were first described in the Hollis and Weaver scheme (Hollis and Weaver, 1981) and, although genetically distinctive and consistent with the definition of the genus *Corynebacterium*, have not been validated as single or multiple species (Funke et al., 1997f). Phylogenetically, several CDC group F-1 strains

Fig. 2. A 24-h culture of “black pigmented *Corynebacterium* sp.” (strain National Microbiology Laboratory [NML] identifier 92-0360) on sheep blood agar.

cluster with “*C. pseudogenitalium*” NCTC 11860 and CDC strain G5911 (Bernard et al., 2000). Isolates are urease producers and lipophilic. CDC group F-1 strains are usually susceptible to penicillin but are often resistant to macrolides.

Coryneform CDC Group G strains also possess features consistent with the genus *Corynebacterium* but could also not be validated as a single or multiple species (Riegel et al., 1995c). Phylogenetically, strains were found to cluster in a clade which includes CDC strain G5840 and “*C. tuberculostearicum*” ATCC 35962 (Bernard et al., 2000). Although phenotypically similar to *C. jeikeium*, these strains can be differentiated by ability to grow anaerobically and to ferment fructose (Riegel et al., 1994; Riegel et al., 1995c). CDC group G isolates are often multiresistant to antibiotics, particularly to macrolides and lincosamides.

Black-pigmented *Corynebacterium* species provisionally called “*C. nigricans*” (Fig. 2) include isolates from a vaginal specimen from a woman with a spontaneous abortion (Shukla et

Fig. 3. Unrooted neighbor-joining tree, generated from a distance matrix calculated using the Kimura 2-parameter model of nucleotide substitution. Numbers at nodes represent bootstrap support values (percentage of 1000 resampled datasets that supported the node in the re-calculated tree). Values below 50% have been omitted. Scale bar represents the approximate genetic distance of 0.01 base substitutions per nucleotide pair.

al., 2001) as well as from a vaginal specimen and a vulvar ulcer (Bernard et al., 2002). These strains have genotypic and chemotaxonomic characteristics consistent with the genus *Corynebacterium*. However, phenotypically, they require differentiation from a "black pigmented" *Rothia*-like taxon first referred to as "CDC Group 4" by Hollis (1992), which phylogenetically falls within the *Rothia* genus (K. Bernard, personal observation).

MICHAEL GOODFELLOW AND LUIS ANGEL MALDONADO

Phylogeny

Actinomycetes with *meso*-diaminopimelic acid (*meso*-A₂pm), arabinose and galactose in the wall peptidoglycan (wall chemotype IV sensu Lechevalier and Lechevalier, 1970a) belong to two markedly distinct aggregate groups (Goodfellow and Minnikin, 1984b; Goodfellow and Lechevalier, 1989b; Goodfellow et al., 1999). Wall chemotype IV actinomycetes containing mycolic acids (high-molecular-weight 3-hydroxy fatty acids with a long alkyl branch in the two position) are classified in the genera *Corynebacterium*, *Gordonia*, *Mycobacterium*, *Nocardia*, *Rhodococcus*, *Skermania*, *Tsukamurella* and *Williamsia*; their mycolateless counterparts are in the family Pseudonocardiaceae (see The Family Pseudonocardiaceae in the second edition). Mycolic acid-containing strains have many properties in common (Goodfellow and Wayne, 1982a; Goodfellow and Cross, 1984a; Goodfellow and Magee, 1998a; Goodfellow et al., 1998; Goodfellow et al., 1999) and form a monophyletic group in the 16S rRNA gene tree (Mordarski et al., 1980b; Stackebrandt and Woese, 1981; Stackebrandt et al., 1983; Stackebrandt et al., 1997; Goodfellow et al., 1998; Goodfellow et al., 1999). Representatives of the mycolic acid-containing genera form distinct subclades in the 16S rRNA gene tree (Fig. 1).

Mycolic acid-containing actinomycetes, and members of the mycolateless genus *Turicella*, are currently assigned to six families on the basis of 16S rRNA gene similarity values and on the distribution of taxon-specific signature nucleotides (Stackebrandt et al., 1997). All of the families belong to the suborder Corynebacterineae, one of the ten suborders of the order Actinomycetales. The family Corynebacteriaceae contains the genera *Corynebacterium* and *Turicella*; the family Dietziaceae, the genus *Dietzia*; the family Gordoniaceae, the genera *Gordonia*, *Skermania* and *Williamsia*; the family Mycobacteriaceae, the genus *Mycobacterium*; the family Nocardiaceae, the genera *Nocardia* and *Rhodococcus*; and the family Tsukamurellaceae, the genus *Tsukamurella*. The present chapter is restricted to a

consideration of the families Dietziaceae, Gordoniaceae, Nocardiaceae and Tsukamurellaceae; the families Corynebacteriaceae (see *Corynebacterium*—Nonmedical in this Volume and The Genus *Corynebacterium*—Medical in this Volume) and Mycobacteriaceae (see *Mycobacterium leprae* in this Volume, The Genus *Mycobacterium*—Medical in this Volume and *Mycobacterium leprae* in this Volume) are considered elsewhere.

Membership of the families Gordoniaceae, Nocardiaceae and Tsukamurellaceae is currently restricted to actinomycetes with the following characteristics: 1) a peptidoglycan composed of *n*-acetylglucosamine, D-alanine, L-alanine, and D-glutamic acid, with *meso*-A₂pm as the diamino acid, and muramic acid in the *n*-glycolated form (Uchida and Aida, 1977; Uchida and Aida, 1979; Uchida and Aida, 1997); 2) a polysaccharide fraction of the wall, rich in arabinose and galactose (whole-organism sugar pattern type A sensu Lechevalier and Lechevalier, 1970b); 3) a phospholipid pattern consisting of diphosphatidylglycerol, phosphatidylethanolamine (a taxonomically significant nitrogenous phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides without phosphatidylcholine or phospholipids containing glucosamine (i.e., phospholipid type 2; Lechevalier et al., 1977; Lechevalier et al., 1981); 4) a fatty acid profile showing major amounts of straight chain, unsaturated fatty acids and tuberculostearic acids (Kroppenstedt, 1985); 5) mycolic acids with 34–78 carbons (Alshamaony et al., 1976a; Alshamaony et al., 1976b; Goodfellow et al., 1978; Goodfellow et al., 1982c); and 6) a DNA G+C content within the range 63–73 mol%. In contrast, strains belonging to the family Dietziaceae have muramic acid in the N-acetylated form and a polar lipid pattern lacking phosphatidylinositol and phosphatidylinositol mannosides (Rainey et al., 1995a).

Some of the major properties of the mycolic acid-containing genera are shown in Fig. 1 and Table 1. Representatives of a number of these taxa have been shown to be closely related using serological techniques (Magnusson, 1976; Pier,

^a Major constituents of wall chemotypes: I, L-A₁pm and glycine; II, meso- A₁pm and glycine; III, meso- A₁pm, arabinose and galactose; IV, meso- A₁pm, arabinose and galactose; V, lysine and ornithine; VI, lysine (with variable presence of aspartic acid and galactose); VII, diaminobutyric acid and glycine (lysine variable); VIII, ornithine; IX, L- and meso- A₂pm. All wall preparations contain major amounts of alanine, glutamic acid, glucosamine and muramic acid (Lechevalier and Lechevalier, 1970, 1980).

^b Whole-organism sugar patterns of actinomycetes containing meso- A₁pm: A, arabinose and galactose; B, madurose (3-O-methyl-D-galactose); C, no diagnostic sugars; D, arabinose and xylose; ND, not applicable (Lechevalier et al., 1971).

^c Peptidoglycan classification (Schleifer and Kandler, 1972; Schleifer and Seidl, 1985). Type A, cross-linkage between positions 3 and 4 of two peptide subunits: 1, direct crosslinkage (no interpeptide bridge); 2, crosslinkage by polymerized peptide bridge; 3, crosslinkage by interpeptide bridges consisting of monocarboxylic L-amino acids or glycine, or both; 4, crosslinkage by interpeptide bridges containing a dicarboxylic amino acid; 5, crosslinkage by interpeptide bridges containing a dicarboxylic amino acid and lysine. Peptidoglycan type B, crosslinkage between positions 2 and 4 of two peptide subunits: 1, interpeptide bridge containing a L-diamino acid; 2, interpeptide bridge containing a D-diamino acid. Small Greek letters mark the diversity of amino acids in position 3 of the peptide subunit. Prime (') indicates the replacement of alanine in position 1 in type A peptidoglycan by glycine (Schleifer and Kandler, 1972; Schleifer and Stackebrandt, 1983; Schleifer and Seidl, 1985).

^d Muramic acid types: A, N-acetylmuramic acid; G, N-glycolymuramic acid (Uchida and Aida, 1977, 1984; Uchida and Seino, 1997).

^e Fatty acid classification after Kropfenstedt (1985). Numbers refer to the type of fatty acid biosynthetic pathway and letters to types of fatty acids (FA) synthesized. Type 1, pathway generating straight-chain fatty acids, including saturated and unsaturated (FA-type 1a), 10-methyl-branched (FA-type 1b) and cyclopropane fatty acids (FA-type 1c), the latter two being derived from the unsaturated compounds. Type 2, pathway yielding terminally-branched fatty acids (FA-type 2), that is, *iso*- and *anteiso*-branched fatty acids. Type 3 encompasses organisms that have complex branched fatty acid types, that is, both 10-methyl-branched (type 1) and *iso*- and/or *anteiso*-branched (type 2) fatty acids.

^f MK-9 (H₂), notation for octahydrogenated menaquinone with nine isoprene units.

^g Characteristic phospholipids: PI, nitrogenous phospholipids absent (with phosphatidylglycerol variable); PII, only phosphatidylethanolamine; PIII, phosphatidylcholine (with phosphatidylethanolamine, phosphatidylmethylethanolamine and phosphatidylglycerol variable); PIV, phospholipids containing glucosamine (with phosphatidylethanolamine variable) and PV, phospholipids containing glucosamine and phosphatidylglycerol (with phosphatidylethanolamine variable); all preparations contain phosphatidylinositol (Lechevalier et al., 1977, 1981).

Fig. 1. Distribution of chemical markers in genera classified in the suborder Corynebacterineae.

1984). The most comprehensive serological studies have used immunodiffusion techniques, and common precipitinogens have been detected among corynebacteria, gordoniae, mycobacteria, nocardiae and rhodococci (Lind and Ridell, 1976; Lind et al., 1980).

The Family Dietziaceae

DIETZIA Rainey et al. 1995, 35^{AL}. This genus was proposed for organisms first known as "*Flavobacterium maris*" (Harrison, 1929) and later as *Rhodococcus maris* (Nesterenko et al., 1982). It currently encompasses three species, *D. maris*, *D. natronolimnais* and *D. psychrhalcaliphilus*, which form a distinct clade in the 16S rRNA Corynebacterineae gene tree (Fig. 2). Dietziae are aerobic, Gram-positive, non-acid-alcohol-fast, non-sporing, catalase-positive actinomycetes, which may form cocci that germinate into short rods or short rod-shaped cells that exhibit snapping division and produce V- forms. Circular, raised or convex, glistening colonies with entire edges are formed on agar media. Pigmentation ranges from orange to coral red. Dietziae are chemoorganotrophs, having an oxidative type

of metabolism. In addition to the aforementioned chemical properties, the organism has an A1γ type peptidoglycan (Schleifer and Kandler, 1972) and contains mycolic acids with 34–39 carbons and up to one double bond. Dihydrogenated menaquinone with eight isoprene units is the major isoprenologue. The G+C content of the DNA is 66–73 mol%. Type species: *Dietzia maris* (Nesterenko et al. 1982) Rainey et al. 1995a, 35^{AL}. Type strain: ATCC 35013^T = DSM 43672^T.

The Family Gordoniaceae

GORDONIA (Tsukamura, 1971a) Stackebrandt et al., 1988, 345^{AL}. This taxon is the type genus of the family Gordoniaceae. The genus was initially known as *Gordonia*; the etymologically correct name, *Gordonia*, was proposed by Stackebrandt et al. (1997). The genus *Gordonia* Tsukamura, 1971a was proposed for some slightly acid-fast actinomycetes isolated from soil and the sputa of patients with pulmonary disease. The three original species, *G. bronchialis*, *G. rubra* and *G. terrae*, were subsequently reclassified in the revised and re-described genus *Rhodococcus* (Tsukamura, 1974a; Goodfellow and Alderson, 1977).

Table 1. Characteristics of members of the mycolic acid-containing genera.

Characters	Genera								
	1	2	3	4	5	6	7	8	9
Cell morphology	Pleomorphic rods, often club-shaped; commonly in angular and palisade arrangement	Short rods and cocci	Rods and cocci or moderately branching hyphae	Rods, occasionally branched filaments that fragment into rods and coccoid elements	Mycelium which later fragments into rods and cocci	Rods to extensively branched mycelium; the latter fragments into irregular rods and cocci	In early stages of growth (24h), substrate mycelium resembles a pine tree	Rods occurring singly, in pairs or in masses; coccobacillary forms produced	Thin irregular rods or cocci that occur singly or in small clusters
Aerial hyphae	Absent	Absent	Absent	Usually absent ^b	Present	Absent	Present	Absent	Present
Time for visible colonies (days)	1–2	1–3	1–3	2–40	1–5	1–3	9–21	1–3	1–4
Degree of acid-fastness (not necessarily also alcohol fastness)	Sometimes weakly acid-fast	Not acid fast	Often partially acid-fast	Usually strongly acid-fast	Often partially acid-fast	Often partially acid-fast	Not acid-fast	Weak to acid-fast	ND
Strictly aerobic	–	+	+	+	+	+	+	+	+
Mycolic acid type ^c	Single spot	Single spot	Single spot	Multiple spots	Single spot	Single spot	Single spot	Two spots	Single spot
Overall size (number of carbons)	22–38	34–38	46–66	60–90	48–60	30–54	58–64	64–78	50–56
Number of double bonds ^d	0–2	0–1	1–4	1–3	0–3	0–2	2–6	1–6	ND
Fatty acid esters released on pyrolysis (number of carbons)	8–18	ND	16–18	22–26	12–18	12–16	16–20	20–22	ND

Symbols: +, positive; –, negative; and ND, not determined.

^aGenera: 1, *Corynebacterium*; 2, *Dietzia*; 3, *Gordonia*; 4, *Mycobacterium*; 5, *Nocardia*; 6, *Rhodococcus*; 7, *Skermania*; 8, *Tsukamurella*; and 9, *Williamsia*.

^b*Mycobacterium farcinogenes* and *Mycobacterium xenopi* may occasionally produce aerial hyphae.

^cNumber of mycolic acid spots produced from whole organism methanolysates (Minnikin et al., 1975, 1984a, b; Hamid et al., 1993; Yassin et al., 1997).

^dIn mycobacterial mycolic acids, double bonds may be converted to cyclopropane rings; methyl branches and other oxygen functions may be present (Minnikin et al., 1984a, b; Dobson et al., 1985).

Data taken from Goodfellow et al. (1998a), Kämpfer et al. (1999), and Nishiuchi et al. (2000).

Fig. 2. Neighbor-joining tree based on nearly complete 16S rRNA gene sequences showing the positions of representative strains of genera classified in the suborder Corynebacterineae. Asterisks indicate branches of the tree that were also found using the least-squares, maximum-likelihood, and maximum-parsimony tree-making algorithms. The numbers at the nodes indicate the levels of bootstrap support (%) based on a neighbor-joining analysis of 1000 re-sampled datasets, and only values above 50% are given. The bar indicates 0.1 substitutions per nucleotide position. T, type strain.

Rhodococcal species were eventually assigned to two aggregate groups on the basis primarily of chemical and serological properties (Goodfellow, 1989a). All species originally classified in the genus *Gordonia* contained mycolic acids with between 48 and 66 carbon atoms and major amounts of dihydrogenated menaquinones with nine isoprene units, whereas the remaining strains were characterized by shorter chain mycolic acids (34–52 carbon atoms) and dihydrogenated menaquinones with eight isoprene units as the predominant isoprenologue (Alshamaony et al., 1976b; Collins et al., 1977; Collins et al., 1985b).

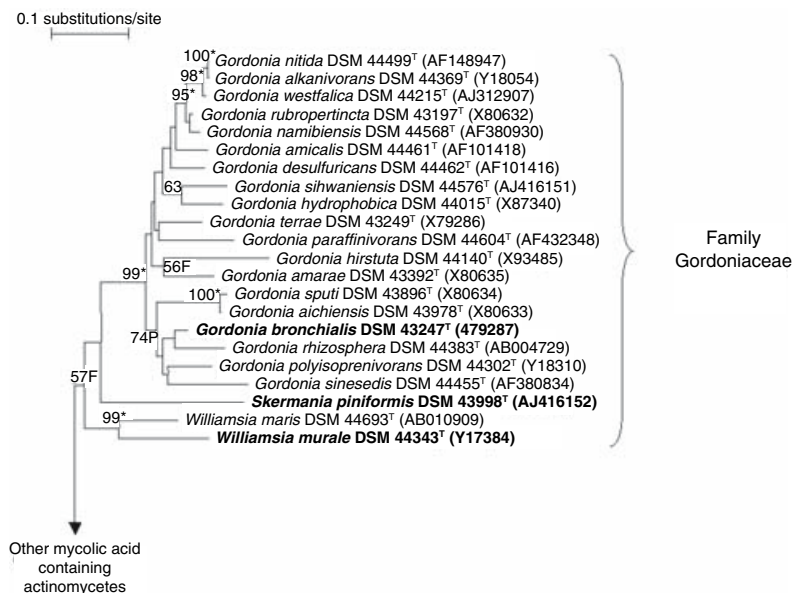

The two aggregate groups were also recognized by their antibiotic sensitivity profiles (Goodfellow and Orchard, 1974), delayed skin reaction on sensitized guinea pigs, and polyacrylamide gel electrophoresis of cell extracts (Hyman and Chaparas, 1977). The discovery that the two aggregate groups were phylogenetically distinct led Stackebrandt et al. (1988) to revive the genus *Gordonia* Tsukamura 1971a for organisms classified as *R. bronchialis*, *R. rubripertincta*, *R. sputi* and *R. terrae*; DNA homology data indicate that *R. obuensis* Tsukamura 1982 should be considered as a subjective synonym of *R. sputa* (Zakrzewska-Czerwinska et al., 1988).

The genus *Gordonia* currently contains nineteen species which form a distinct clade within the evolutionary radiation encompassed by mycolic acid-containing actinomycetes (Figs. 2

and 3). The taxonomic status of most of these species is underpinned by a wealth of genotypic and phenotypic data (Linos et al., 1999; Kim et al., 2000; Brandão et al., 2001). However, further studies are required to determine the finer relationship between *G. alkalivorans* and *G. nitida*, as the type strains of these species share a 16S rRNA gene similarity of 99.9%, a value which corresponds to two nucleotide differences at 1480 locations (Maldonado et al., 2003).

Gordoniae are aerobic, Gram-positive to Gram-variable, catalase positive, partially acid-alcohol-fast, nonmotile actinomycetes that form short rods and cocci that occur singly, in pairs, in V-shaped arrangements or in short chains. Colonial appearance ranges from convex, shiny and smooth to rough, matt and folded with irregular margins. Pigmentation may be pale yellow, beige or tan through to orange pink or red. The organism has an oxidative type of metabolism, is aryl-sulfatase negative, sensitive to lysozyme, and produces mycobactins. In addition to the chemical properties mentioned earlier, the organism has an A1γ type of peptidoglycan, contains dihydrogenated menaquinones with nine isoprene units as the predominant isoprenologue and has mycolic acids with 46–66 carbons with one to four double bonds. The fatty acid esters released on pyrolysis gas chromatography of mycolic esters contain 16–18 carbon atoms. The G+C content of the DNA is 63–69 mol%. Type species: *Gordonia bronchialis* (Tsukamura, 1971a)

Fig. 3. Neighbor-joining tree based on nearly complete 16S rRNA gene sequences showing relationships between representative strains of the family Gordoniaceae. Asterisks indicate branches of the tree that were also found using the least-squares, maximum-likelihood, and maximum-parsimony tree-making algorithms. The numbers at the nodes indicate the levels of bootstrap support (%) based on a neighbor-joining analysis of 1000 re-sampled datasets, and only values above 50% are shown. F and P indicate branches that were also recovered using the least-squares and maximum-parsimony methods, respectively. The bar indicates 0.1 substitutions per nucleotide position. T, type strain.

Stackebrandt et al. 1988, 345^{AL}. Type strain: ATCC 25592^T = DSM 43247^T.

SKERMANIA Chun et al., 1997, 129^{AL}. This genus contains a single species, *Skermania piniformis*, which falls towards the periphery of the 16S rRNA Gordoniaceae gene tree (Figs. 1 and 3). The taxon was proposed for actinomycetes first known as “Pine Tree-Like Organisms” (PTLO; Blackall et al., 1998) and later as “*Nocardia pinensis*” (Blackall et al., 1989b). The appellation PTLO was given to these organisms as they formed a distinctive tree-like microscopic morphology; branches are acute- rather than right-angled, and those near the apex are shorter than those farther away. The characterization of *S. piniformis* was based on a few strains and a small number of physiological tests, but since then larger numbers of strains with morphology typical of PTLO have been shown to have a unique API ZYM pattern (Soddell and Seviour, 1994). In an extensive numerical taxonomic study, such strains were recovered in a homogeneous cluster which contained the type strain of *S. piniformis* (Soddell and Seviour, 1998).

Skermania are aerobic, Gram-positive, non-acid-fast, nonmotile actinomycetes which form an extensive mycelium that does not fragment in undisturbed culture; secondary branching is rare or absent. Aerial hyphae are not visible to the naked eye, but short branched and unbranched aerial hyphae can be seen microscopically. The microscopic appearance of the organism resembles a pine tree during early stages of growth (24 h). Cells from activated sludge plants or from artificial culture media contain intracellular sudanophilic and polyphosphate inclusions. Colonies (1–2 mm in diameter) form on tryptone-yeast extract-glucose agar within 10–21 days,

although the growth rate is variable. Colonies are orange, opaque, macroscopically dry and friable, and microscopically moist and slimy, have a pasty texture, are difficult to emulsify or subculture, and are circular with entire edges. When picked from the agar surface, a whole colony can be removed intact. Strains grow well on media that contain glycerol as a carbon source and asparagine as a nitrogen source. In tryptic yeast extract glucose broth, strains grow as macroscopically visible colonies in a slightly turbid liquid. The maximum and minimum growth temperatures are 31°C and 15°C, respectively. Growth is not enhanced in an atmosphere containing 4% CO₂, nor does growth occur anaerobically, microaerophilically, or in a candle jar. Strains have an oxidative metabolism and are catalase, oxidase, and urease positive.

In addition to the chemical properties mentioned earlier, the organism has an A1γ peptidoglycan and contains mycolic acids with 58–64 carbons with 2–6 double bonds and substantial numbers of unsaturated chains in the 2-position. The fatty acid esters released on pyrolysis gas chromatography of mycolic acids contain 16–20 carbon atoms. Predominant amounts of hexahydrogenated menaquinone with eight isoprene units are produced in which the two end units are cyclized. The G+C content of the DNA is 67.5%, as determined by the thermal denaturation method. Type species: *Skermania piniformis* Chun et al., 1997, 129^{AL}. Type strain: DSM 43998^T = IFO 15059^T.

WILLIAMISIA Kämpfer et al., 1999, 686^{AL}.

This taxon was proposed to accommodate an aerobic, Gram-positive, non-acid-alcohol-fast, chemoheterotrophic actinomycete that forms short rods and coccoid-like elements. Peritric-

hous fibrillae distributed over the whole surface of cells are visible by transmission electron microscopy but not in negatively stained preparations. The temperature range for growth is 10–37°C. In addition to the chemical markers mentioned earlier, the organism contains mycolic acids with 50–56 carbon atoms and dihydrogenated menaquinones with nine isoprene units as the predominant isoprenologue. The G+C content of the DNA is 64–65 mol%. Type species: *Williamsia muralis* Kämpfer et al. 1999, 686^{AL}. Type strain: DSM 44343^T = MA140/96^T.

A second species, *W. maris*, has been described for a strain isolated from the Sea of Japan (Stach et al., 2004); this organism was initially considered to be closely related to the genus *Gordonia* (Colquhoun et al., 1998). The type strains of the two *Williamsia* species form a distinct clade towards the margin of the 16S rRNA *Gordoniaceae* gene tree.

The Family Nocardiaceae

NOCARDIA Trevisan, 1889, 9^{AL}. Nocardiae are aerobic, Gram-positive, non-motile catalase-positive actinomycetes that are typically acid-alcohol-fast at some stages of the growth cycle. They form rudimentary to extensively branched substrate hyphae that often fragment in situ or, on mechanical disruption, disrupt into rod-shaped to coccoid, nonmotile elements. Aerial hyphae, at times visible only microscopically, are almost always present. Short-to-long chains of well-to-poorly differentiated conidia may occasionally be found on aerial hyphae and, more rarely, on both aerial and substrate mycelia. Most nocardiae form carotenoid-like pigments that confer various shades of orange, pink, red or yellow to colonies growing on solid culture media. Soluble brown or yellowish diffusible pigments may be produced. Colony morphology is variable; it may be smooth to granular and irregular, wrinkled or heaped. The presence of aerial hyphae often confers a powdery or velvety appearance to the surface of colonies. Nocardiae are chemoorganotrophic and have an oxidative type of metabolism. In addition to the chemical properties already mentioned, the nocardial peptidoglycan is of the A1γ type. The organism contains mycolic acids with 40–64 carbon atoms and up to three double bonds; the fatty acid esters released on pyrolysis gas chromatography of mycolic esters contain 12–18 carbon atoms and may be saturated or unsaturated. The predominant menaquinone corresponds to a hexahydrogenated menaquinone with eight isoprene units in which the end two units are cyclized (i.e., II, III-tetrahydro-ω-[2, 6, 6-trimethylcyclohex-2-en-ylmethyl] menaquinone-6). The G+C content of the DNA is 64–72 mol%.

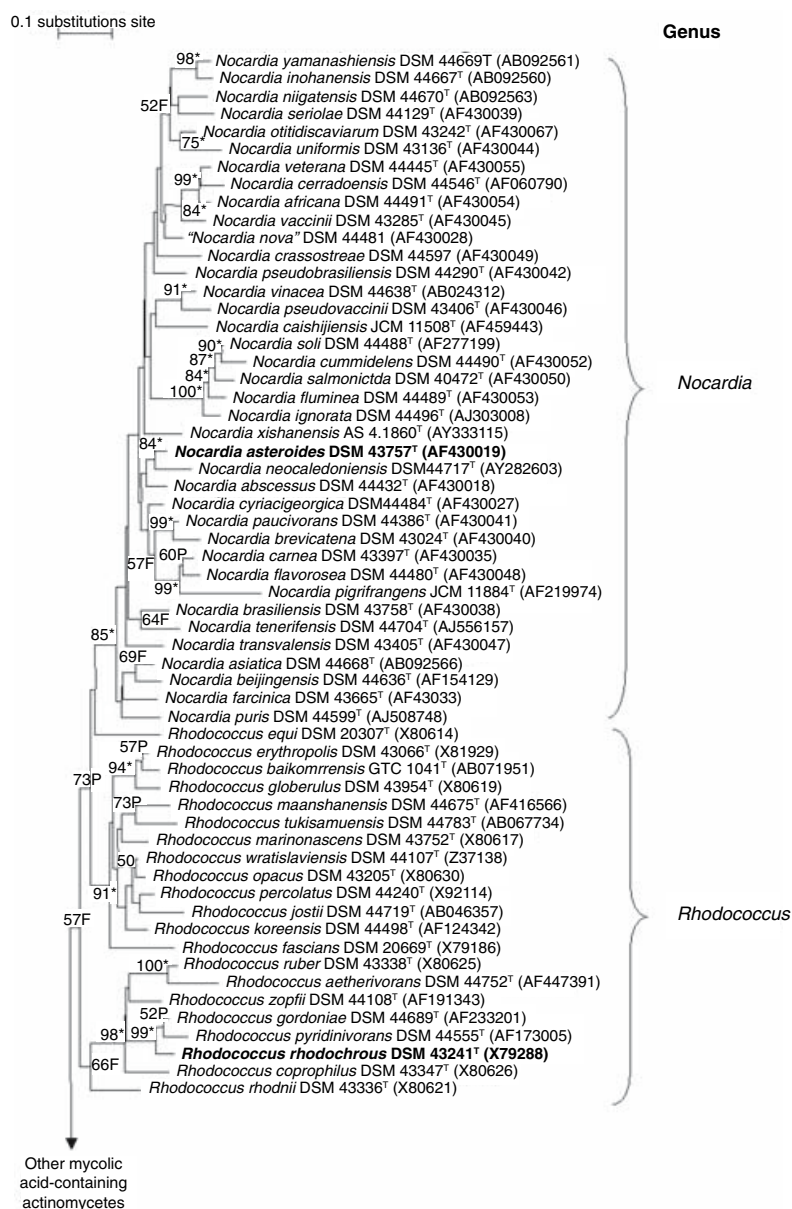

Type species: *Nocardia asteroides* (Eppinger 1891) Blanchard 1896, 856^{AL}, Opinion 58, Judicial Commission 1985, 538. Type strain: ATCC 19247^T = DSM 43757^T.

The genus *Nocardia* presently includes 38 species, which form a well-delineated clade in the 16S rRNA *Corynebacterineae* gene tree (Figs. 1 and 4). Nearly half of these species have been described within the last five years mainly to accommodate organisms isolated from clinical material (Gürtler et al., 2001b; Hamid et al., 2001; Kageyama et al., 2003a; Kageyama et al., 2003b; Yassin et al., 2003) and environmental samples, notably soil (Albuquerque de Barros et al., 2003; Kämpfer et al., 2003; Saintpierre-Bonaccio et al., 2003; Zhang et al., 2004). The taxonomic status of the recently described species is based on a balance set of genotypic and phenotypic criteria. There are good grounds for considering more established species such as *N. brasiliensis*, *N. otitidiscaviarum* and *N. seriola* to be well circumscribed taxa (Gordon and Mihm, 1962; Goodfellow, 1971; Kudo et al., 1988). In contrast, *N. asteroides* has been shown to be heterogeneous on the basis of DNA homology (Mordarski et al., 1977; Mordarski et al., 1978; Bradley et al., 1978b), numerical taxonomic (Tsukamura, 1969; Tsukamura, 1982b; Goodfellow, 1971; Schaal and Reutersberg, 1978b; Orchard and Goodfellow, 1980; Goodfellow et al., 1998), phage sensitivity (Pulverer et al., 1975) and immunological (Pier and Fichtner, 1971; Magnusson, 1976; Kurup and Schribner, 1981; Ridell, 1981) data.

There is evidence that some clinically significant strains identified as *N. asteroides* and *N. farcinica* belong to different species (Wallace et al., 1990; Workman et al., 1998; Roth et al., 2003). One such species, “*N. nova*,” is cited as species incertae sedis in the current edition of *Bergey's Manual of Determinative Bacteriology* (Goodfellow and Lechevalier, 1989b). Yano et al. (1990) separated “*N. nova*” from *N. asteroides* and *N. farcinica* strains using DNA-DNA relatedness, mycolic acid, and numerical taxonomic data. *Nocardia nova* strains also have a distinctive antimicrobial sensitivity pattern (Wallace et al., 1991). Despite the rapid expansion in the number of *Nocardia* species, additional nocardial diversity has still to be described (Wang et al., 1999; Maldonado et al., 2000; Roth et al., 2003).

RHODOCOCCUS (Zopf, 1891) EMEND. Goodfellow et al. 1998, 11^{AL}. Rhodococci have a long and checkered taxonomic history, which is described in several review articles (Bousfield and Goodfellow, 1976; Goodfellow and Cross, 1984a; Goodfellow et al., 1998). The genus, with *R. rhodochrous* as the type species, was recognized in the early editions of *Bergey's Manual of Determinative Bacteriology* (Bergey et al., 1923,

Fig. 4. Neighbor-joining tree based on nearly complete 16S rRNA gene sequences showing relationships between representative strains of the family Nocardiaceae. Asterisks indicate branches of the tree that were also found using the least-squares, maximum-likelihood, and maximum-parsimony tree-making algorithms. The numbers at the nodes indicate the levels of bootstrap support (%) based on a neighbor-joining analysis of 1000 re-sampled datasets, and only values above 50% are shown. F and P indicate branches that were also recovered using the least-squares and maximum-parsimony methods, respectively. The bar indicates 0.1 substitutions per nucleotide position. T, type strain.

1925, 1930, and 1934). However, rhodococcal species were transferred to the genus *Micrococcus* in the fifth edition of *Bergey's Manual of Determinative Bacteriology* (Bergey et al., 1939) and remained there in the following edition (Breed et al., 1948). Rhodococcal-like strains were also assigned to an assortment of other morphologically defined genera during this time. Indeed, only with the far-reaching changes that occurred in the taxonomy of Gram-positive cocci and mycolic acid-containing strains in light of new developments in bacterial systematics did attention focus on rhodococci.

The epithet *rhodochrous* (Zopf, 1891) was resurrected by Gordon and Mihm (1957) for actinomycetes bearing a multiplicity of generic and

specific names but with many properties in common with mycobacteria and nocardiae. The taxon was provisionally assigned to the genus *Mycobacterium* but was later considered to merit generic status. The genus *Rhodococcus* was eventually reintroduced (Tsukamura, 1974a; Goodfellow and Alderson, 1977) and encompasses 16 species in the current edition of *Bergey's Manual of Systematic Bacteriology* (Goodfellow, 1989a). Most of these were circumscribed in numerical taxonomic surveys (Goodfellow and Alderson, 1971; Tsukamura, 1974a; Rowbotham and Cross, 1977b; Goodfellow et al., 1982b; Goodfellow et al., 1982d) and later shown to be homogeneous on chemical and molecular systematic grounds (Minnikin and

Goodfellow, 1980a; Mordarski et al., 1980a; Zakrzewska-Czerwinska et al., 1988).

The reintroduction of the genus *Gordonia* and the recognition of the genus *Dietzia* left the genus *Rhodococcus* as a taxon encompassing aerobic, Gram-positive to Gram-variable, non-motile, catalase-positive actinomycetes that are usually partially acid-alcohol-fast at some stage in the growth cycle and which form rods to extensively branched substrate-mycelia. The growth cycle starts with the coccus or short rod stage, and then different organisms show a more or less complex series of morphological stages: cocci may germinate only into short rods or form filaments with side projections, or show elementary branching, or (in the most differentiated forms) produce branched hyphae. The next generation of cocci or short rods is produced by fragmentation of the rods, filaments and hyphae. Some strains produce sparse, microscopically visible, aerial hyphae that may be branched or form synnemata, which consist of unbranched filaments that coalesce and project upwards.

Rhodococci grow well on standard laboratory media at 30°C although some strains require thiamine. Colonies may be rough, smooth or mucoid, and pigmented buff, cream, yellow, orange or red, though colorless variants occur. Rhodococci are catalase positive, sensitive to lysozyme, arylsulfatase negative, and produce acid from glucose oxidatively. In addition to the chemical properties mentioned earlier, the rhodococcal peptidoglycan belongs to the A1γ type and contains mycolic acids with 30–54 carbons and up to two double bonds. The fatty acid esters released on pyrolysis gas chromatography of mycolic esters have 12–16 carbon atoms. In addition, rhodococci contain dihydrogenated menaquinones with eight isoprene units as the predominant isoprenologue. The G+C content of the DNA is 67–73 mol%. Type species: *Rhodococcus rhodochrous* (Zopf, 1889) Tsukamura 1974, 43^{AL}. Type strain: ATCC 13808^T = DSM 43241^T.

The improved classification of the genus *Rhodococcus* provides a sound basis for the recognition of additional *Rhodococcus* species. The genus currently contains 19 species that form a recognizable group within the evolutionary radiation occupied by mycolic acid containing actinomycetes (Figs. 1 and 4). The taxonomic integrity of rhodococcal species is supported by a combination of genotypic and phenotypic properties (Goodfellow et al., 2004; Jones et al., 2004; Li et al., 2004). Rhodococcal species can be assigned to four 16S rRNA gene subclades (Rainey et al., 1995b; Goodfellow et al., 1998) that have been equated with the rank of species (Goodfellow et al., 1998; McMinn et al., 2000).

The Family Tsukamurellaceae

TSUKAMURELLA Collins et al., 1989, 387^{AL}. This taxon was introduced for organisms classified as *Corynebacterium paurometabolum* and *Rhodococcus aurantiacus*. *Corynebacterium paurometabolum* was proposed by Steinhaus (1941) for bacteria isolated from the mycetome and ovaries of the bedbug (*Cimex lectularis*), but its placement in the genus *Corynebacterium* was questioned (Jones, 1975; Collins and Jones, 1982a). The organism has an A1γ peptidoglycan (Cummins, 1971; Schleifer and Kandler, 1972) but was distinguished from corynebacteria by the presence of long, highly unsaturated, mycolic acids (Collins and Jones, 1982a). A similar series of unsaturated mycolic acids was detected in *Rhodococcus aurantiacus* (Goodfellow et al., 1978; Tomiyasu and Yano, 1984), the generic position of which was also equivocal (Goodfellow, 1989a). This species, first described as *Gordonia aurantiaca* (Tsukamura and Mizuno, 1971b), was later reclassified in the genus *Rhodococcus* (Tsukamura, 1974a; Tsukamura and Yano, 1985). In contrast, Goodfellow et al. (1978) considered that *aurantiaca* strains were worthy of generic status as they formed a numerically circumscribed taxon equivalent in rank to the genera *Corynebacterium*, *Mycobacterium*, *Nocardia* and *Rhodococcus* and contained characteristic mycolic acids and unsaturated menaquinones with nine isoprene units. *Corynebacterium paurometabolum* was also found to have menaquinones containing unsaturated multiprenyl side chains (Collins and Jones, 1982a).

Corynebacterium paurometabolum and *Rhodococcus aurantiacus* were reduced to a single species and reclassified in the genus *Tsukamurella* using 16S rRNA sequence data and the results of the experiments outlined above (Collins et al., 1989). The genus accommodates aerobic, Gram-positive, partially acid-alcohol-fast, nonmotile, nonsporeforming actinomycetes that form straight to slightly curved rods that occur singly, in pairs or in masses; coccobacillary elements also occur. The organism forms white-creamy to orange convex colonies that are dryish but easily emulsified. Tsukamurellae are catalase-positive, are arylsulfatase negative, are resistant to lysozyme, and produce acid from glucose oxidatively. In addition to the chemical properties mentioned earlier, the organism has an A1γ peptidoglycan and highly unsaturated long chain mycolic acids with 64–78 carbon atoms and one to six double bonds. The fatty acids released on pyrolysis mass spectrometry of mycolic esters have 22–26 carbons. Menaquinones are the sole respiratory quinone with unsaturated components with nine isoprene units predominating. The G+C content of the DNA is 67–74 mol%.

Type species: *Tsukamurella paurometabola* (Steinhaus, 1941) Collins et al. 1989^{AL}. Type strain: ATCC 8368^T = DSM 20162^T.

The genus encompasses seven species, which form a distinct clade within the evolutionary radiation occupied by members of the suborder Corynebacterineae. Representatives of these taxa share very high 16S rRNA gene similarity values (>99.5%) but were delineated using DNA-DNA relatedness and phenotypic data (Kattar et al., 2001; Nam et al., 2003). The taxonomic integrity of *T. inchonensis* (Yassin et al., 1995), *T. pseudospumae* (Nam et al., 2004b), *T. pulmonis* (Yassin et al., 1996), *T. spumae* (Nam et al., 2003), *T. strandjordii* (Kattar et al., 2001) and *T. tyrosinosolvens* (Yassin et al., 1998) has been underpinned by the results of an extensive polyphasic taxonomic study (Nam, 2004a). Also, this investigation indicates that *T. paurometabola* is a heterogeneous taxon and that the genus *Tsukamurella* is underspeciated. An additional species, “*T. sunchonensis*” Seong et al. 2003, has yet to be validated.

Habitat

The Family Dietziaceae

Dietzia maris strains have been isolated from soil, the skin and intestinal tract of carp, and deep-sea sediments in the Pacific Ocean (Nesterenko et al., 1982; Rainey et al., 1995a; Colquhoun et al., 1998). In turn, *D. natronolimnaios* was isolated from a moderately saline and alkaline East African soda lake (Duckworth et al., 1998) and *D. psychrhalcaliphilus* from a drain pool of a fish egg-processing plant (Yumoto et al., 2002). The first documented evidence implicating *D. maris* as an agent of disease involved a catheter-associated bacteremia in an immunocompromised male patient (Bemer-Melchior et al., 1999). The organism has also been isolated from a bone infection (Pidoux et al., 2001).

The Family Gordoniaceae

Gordonia strains are widely distributed in soil and aquatic habitats, including marine sediments (Tsukamura, 1971a; Colquhoun et al., 1998; De los Reyes et al., 1998a; De los Reyes et al., 1998b; Kim et al., 2000). In addition, gordoniae have been isolated from rhizosphere soil (Takeuchi and Hatano, 1998), biofilters (Bendinger et al., 1995), industrial wastewater (Yoon et al., 2000c), wastewater treatment bioreactors (Kim et al., 2003), and activated sludge in aeration tanks of biological sewage-treatment plants (Lemmer and Kroppenstedt, 1984). Large numbers of gordoniae have been isolated from foaming activated sludge plants in various parts of the world

(Lechevalier and Lechevalier, 1974; Goodfellow et al., 1996; Goodfellow et al., 1998; Stainsby et al., 2002); *G. amarae* is regarded as a major component of the bacterial community responsible for foaming in such plants (Dhaliwal, 1979; Sezgün et al., 1988; Blackall et al., 1989b; Blackall et al., 1991; De los Reyes et al., 1998a; De los Reyes et al., 1998b). This organism produces a surfactant and cells that are very hydrophobic (Blackall and Marshall, 1989a).

Gordoniae are being increasingly encountered as agents of human infection, but even so their superficial resemblance to more common aerobic actinomycete pathogens, notably mycobacteria and nocardiae, has probably resulted in inadequate diagnosis and hence an underestimation of their clinical significance. *Gordonia bronchialis* and *G. sputi* have been isolated from sputa of patients with pulmonary disease, including bronchiectasis and cavitary pulmonary tuberculosis (Tsukamura, 1971a; Tsukamura, 1978; Tsukamura and Yano, 1985; Guagnani et al., 1998); members of the former taxon caused a nosocomial outbreak of sternal wound infections in patients following coronary artery bypass surgery (Richet et al., 1991) and bacteremia in a patient with a sequestered lung (Sng et al., 2004). A *Gordonia* strain, related to *G. sputi*, has been implicated in a case of endocarditis in a young woman with a central venous catheter (Lesens et al., 2000). The first recorded case involving *G. rubripertincta* was a lung infection in a young immunocompromised woman where an initial diagnosis was confused with tuberculosis (Hart et al., 1988). Gordoniae, especially *G. terrae*, has been reported to cause central venous catheter related bacteremia (Buchman et al., 1992; Pham et al., 2003), infections of the central nervous system (Drancourt et al., 1994; Drancourt et al., 1997), and cutaneous infections (Martin and Hogan, 1991; Lasker et al., 1992). *Gordonia sputi* has been implicated as a causal agent of mesenteric lymphadenitis of the ileum of a six-year-old pig (Tsukamura et al., 1988).

Skermania piniformis has been found to be abundant in foams on the surface of aeration tanks in activated sludge plants, a feature it has in common with *G. amarae* (Blackall et al., 1989b; Blackall et al., 1989b; Soddell and Seviour, 1994; Soddell and Seviour, 1998). However, unlike *G. amarae* this organism has not been isolated from any other habitat. Little is known about the distribution of *Williamsia*, as only two strains have been isolated to date. *Williamsia muralis* DSM 44343^T was isolated from indoor building material in the wall of a child day care center in Finland (Kämpfer et al., 1999) and *W. maris* DSM 44693^T from sediment collected from the Sea of Japan (Stach et al., 2004).

The Family Nocardiaceae

Members of the family Nocardiaceae are common and widely distributed in aquatic and terrestrial habitats, but some are opportunistic pathogens for animals, including humans. Nocardiaceae strains are probably involved in the turnover of organic matter in natural habitats though little is known about their roles therein. Developments in molecular ecology and selective isolation procedures can be expected to yield information on their occurrence, distribution, numbers and activity in natural habitats.

NOCARDIAE AS ANIMAL PATHOGENS.

Nocardiae cause several types of suppurative infections in humans (Schaal and Beaman, 1984; Boiron et al., 1993; Boiron et al., 1998; McNeil and Brown, 1994; Goodfellow 1995; Goodfellow 1997; Schaal, 1997; Beaman, 2000a; Beaman, 2002). Infection may occur by inhalation and through contaminated wounds and traumatic implantations. Five forms of disease are recognized, namely, pulmonary nocardiosis; systemic nocardiosis involving two or more body sites; nocardiosis of the central nervous system; extrapulmonary nocardiosis; and cutaneous, subcutaneous and lymphocutaneous nocardiosis (Schaal, 1997). This division is justified from clinical and therapeutic perspectives and is a development of an earlier scheme (Schaal and Beaman, 1984).

Most pulmonary infections in nontropical countries are caused by *N. asteroides*, *N. farcinica* and "*N. nova*"; relatively few are caused by *N. brasiliensis*, *N. otitidiscaviarum*, *N. pseudotuberculosis* and *N. transvalensis*. Hamid et al. (2000) described *N. africana* for strains isolated from sputum samples taken from patients with pulmonary disease at the Chest Unit of Khartoum Teaching Hospital in the Sudan. There have been isolated reports of pulmonary nocardiosis from other tropical countries caused by *N. asteroides*, *N. farcinica*, *N. otitidiscaviarum* and *N. transvalensis* (Osoagbaka et al., 1985; McLeod et al., 1989; Koffi et al., 1998). Cutaneous and subcutaneous infections are caused by *N. asteroides* and *N. brasiliensis* and to a lesser extent by *N. farcinica*, *N. otitidiscaviarum* and *N. transvalensis*. Strains isolated from abscesses have been described as *N. abscessus* (Yassin et al., 2000), *N. puris* (Yassin et al., 2003), and as *N. niigatensis* and *N. yamanashinensis* (Kageyama et al., 2003b). Some nocardiae are agents of actinomycetoma, a localized, chronic and progressive infection of the skin and subcutaneous tissue (Mahgoub and Murray, 1973) which is endemic in many tropical and subtropical regions of the world. The main nocardial agent of this disease is *N. brasiliensis*; *N. asteroides* and *N. otitidiscaviarum* are occasionally involved.

Nocardiae cause infections in a wide range of animals (Beaman and Sugar, 1983; Beaman and Beaman, 1994). Animals susceptible to nocardial infections include birds, cats, cattle, chickens, dogs, ducks, fish, goats, guinea pigs and sheep. Pulmonary and systemic nocardioses, including infections of the brain, are the most frequently recognized conditions, but cutaneous and mycetomatous lesions also occur. In dairy animals, notably cows, nocardial mastitis can be a major problem (Bushnell et al., 1979; Battig et al., 1990; Stark and Anderson, 1992; Manninen et al., 1993; Da Costa et al., 1996). Strains involved in the Canadian epizootic were tentatively identified as *N. farcinica* (Manninen et al., 1993). The most frequently recognized pathogen of animals is *N. asteroides* followed by *N. brasiliensis* and *N. otitidiscaviarum*. *Nocardia crassostreae* has been isolated from infections in oysters (Friedman et al., 1998) and *N. seriolae* from those in fish (Kudo et al., 1988).

NOCARDIAE AS SAPROPHYTES, SYMBIONTS AND PLANT PATHOGENS. Nocardiae are common in soil (Cross et al., 1976); populations up to 7.3×10^4 /g dry weight have been found in environmental samples from tropical and temperate regions (Orchard et al., 1977). They also form mutualistic associations with blood-sucking arthropods and occur in aquatic habitats (Cross et al., 1976), where they have been implicated in the biodeterioration of natural rubber joints in water and sewage pipes (Hutchinson et al., 1975; Maldonado et al., 2000). Most isolates from these habitats have been identified as *N. asteroides*, but the application of improved methods for delineating nocardial species has led to novel soil isolates being classified as *N. beijingensis* (Wang et al., 2001), *N. caishijiensis* (Zhang et al., 2003), *N. cerradoensis* (Albuquerque de Barros et al., 2003), *N. cummidelens* (Maldonado et al., 2000), *N. fluminea* (Maldonado et al., 2000), *N. soli* (Maldonado et al., 2000), *N. tenerifensis* (Kämpfer et al., 2004), *N. vinacea* (Kinoshita et al., 2001), and *N. xishanensis* (Zhang et al., 2004). *Nocardia asteroides* and *N. otitidiscaviarum* have been isolated from foaming sewage treatment plants of the activated sludge type (Lechevalier and Lechevalier, 1974; Lechevalier et al., 1977; Blackall et al., 1988; Blackall et al., 1989b). *Nocardia vaccinii*, the only well known plant pathogen, causes galls in blueberry (Demaree and Smith, 1952).

RHODOCOCCIAS SAPROPHYTES, SYMBIONTS AND PATHOGENS. Rhodococci are widely distributed in aquatic and terrestrial habitats. They have been isolated from soil, marine sediments, and from the gut contents of blood-sucking arthropods with which they may form a mutualistic association (Cross et al., 1976; Goodfellow and Aubert, 1980; Colquhoun et al., 1998;

Zhang et al., 2002). *Rhodococcus erythropolis*, *R. rhodochrous* and *R. ruber* have been isolated from soil (Goodfellow and Williams, 1983), *R. marinonascens* from marine sediments (Helmke and Weyland, 1984), and *R. rhodochrous* from foam on the surface of aeration tanks in activated sludge plants (Lemmer and Kroppenstedt, 1984). They have also been recovered from more restricted sources, as exemplified by the isolation of *R. baikonurensis* from air in the Russian space laboratory Mir (Li et al., 2004), *R. gordoniae* from phenol contaminated soil (Jones et al., 2004), *R. jostii* from a medieval grave (Takeuchi et al., 2002), and *R. koreensis* and *R. pyridinivorans* from industrial wastewater (Yoon et al., 2002b; Yoon et al., 2002c).

Rhodococcus coprophilus has been the subject of more extensive ecological studies (Rowbotham and Cross, 1977a). This organism grows on herbivorous dung, but high numbers have also been recorded from grazed pastures and from rivers, streams, and lake muds that receive runoff from land devoted to dairy farming. The coccal survival stage seems to contaminate grass in pastures or hay used during the winter months for fodder and remains viable after ingestion and passage through the rumen. The significant correlation found between the numbers of *R. coprophilus* and fecal streptococci (enterococci) in polluted water led Al-Diwany and Cross (1978) to the view that the organism be considered an indicator of farm animal effluent, a view shared by others (Mara and Oragui, 1981; Oragui and Mara, 1985).

The clinical presentation of rhodococcal infections in humans is influenced by the immune status of the host and the virulence of the infecting organism. The first documented human infection involved a patient suffering from *R. equi* pneumonia who had been given corticosteroid therapy for chronic hepatitis (Golub et al., 1967). Later reports of human infection have underpinned the role of rhodococci as agents of pulmonary disease in severely immunocompromised individuals (McNeil and Brown, 1994). Other rhodococci implicated in pathogenic processes include *R. erythropolis*, *R. globerulus*, *R. luteus*, *R. rhodnii* and *R. rhodochrous* (Altire-Werber et al., 1968; Haburchack et al., 1978; Broughton et al., 1981; Von Below et al., 1991; Cuello et al., 2002).

Rhodococcus equi has long been recognized as an important veterinary pathogen that causes bronchopneumonia, lymphadenitis, and ulcerative enteritis in foals (Barton and Hughes, 1980; Prescott, 1991). Reports of *R. equi* infections in humans, once rare, are increasing in frequency (Scott et al., 1995; Kedlaya et al., 2001; Weinstock and Brown, 2002). Indeed, members of this species have been identified as agents of invasive

pulmonary infections in severely immunosuppressed patients, in particular those with acquired immunodeficiency syndrome (AIDS; McNeil and Brown, 1994; Arlotti et al., 1996). Drancourt et al. (1992) reported 51 infections due to *R. equi*, 20 of which came from human immunodeficiency virus (HIV)-patients and 9 from immunocompetent individuals; they also noted that patients infected with *R. equi* frequently had a history of contact with farm animals.

The Family Tsukamurellaceae

Tsukamurellae have been isolated from activated sludge, arthropods, clinical material and soil (Steinhaus, 1941; Tsukamura and Mizuno, 1971b; Goodfellow et al., 1998; Larkin et al., 1999). They have also been reported to cause catheter-associated sepsis, cutaneous infections, meningitis and pulmonary disease. Respiratory tract colonization occurs in immunocompromised and non-immunocompromised patients, notably those with underlying chronic lung diseases. Tsukamura and Kawakami (1982c) were the first to note the pathogenic role of *Tsukamurella* strains in humans when they repeatedly recovered a pure culture of *T. paurometabola* from the sputa of a patient with a tuberculosis-like disease. This organism has been associated with individual cases of lethal meningitis (Prinz et al., 1985), severe gangrenous tendosynovitis with multiple subcutaneous abscesses (Tsukamura et al., 1988a), and catheter-related bacteremia (Shapiro et al., 1992). Additional cases of catheter-related bacteremia have been attributed to *T. pulmonis* and *T. tyrosinosolvens* (Maertens et al., 1988; Schwartz et al., 2002; Sheridan et al., 2003). Members of these taxa, together with *T. inchonensis*, have been reported to cause lung infections (Yassin et al., 1995; Yassin et al., 1996; Yassin et al., 1997). *Tsukamurella strandjordii* was isolated from blood cultures of a child with acute myelogenous leukemia (Kattar et al., 2001). A pseudoinfection caused by *T. paurometabola* strains was traced back to laboratory contamination (Auerbach et al., 1991).

Isolation and Cultivation

The Family Dietziaceae

Dietzia maris was isolated from soil and the skin and intestinal contents of carp (*Cyprinus carpio*) on mineral salts agar enriched with *n*-alkanes and incubated at 28°C (Nesterenko et al., 1982), and *D. natronolimnaios* was isolated from dilutions of sediment samples made in alkaline broth; the latter was then plated out onto alka-

line agar media prior to incubation at 37°C (Duckworth et al., 1998). *Dietzia psychralcaliphila* was isolated from water (6°C, pH 7) obtained from a drain pool of a fish processing plant using a synthetic medium (AT medium) which was supplemented with vaporized *n*-tetradecane as the sole carbon source; inoculated plates were incubated at 4°C for a month (Yumoto et al., 2002).

The Families Gordoniaceae and Tsukamurellaceae

A chemical pretreatment combined with a selective medium has been developed for the isolation of gordoniae and tsukamurellae from sputa and soils (Tsukamura, 1971a; Tsukamura et al., 1988a). Samples and specimens suspended in distilled water (25 ml) are added to an equal volume of NaOH (4%) and liquefied, either by incubation at 37°C for 30 min or by shaking at room temperature for 15–30 min. The digests are inoculated onto Ogawa egg medium (Tsukamura, 1972) and incubated for 4–8 weeks.

For soil samples, soil (5 g) is suspended in distilled water (25 ml) and shaken vigorously in a 300-ml Erlenmeyer flask at room temperature on a reciprocal shaker (stroke: 10 cm, 60 cpm) for 30 min. The suspension is allowed to settle for 10 min, 15 ml of the supernatant is added to an equal volume of NaOH (8%), and the mixture is shaken for 10 min before centrifugation at $500 \times g$ for 15 min. The residue is suspended in 10 ml of a 1% NaH_2PO_4 solution, and 0.002 ml is added to Ogawa egg medium slants, which are incubated for 4–8 weeks.

Colonies growing on the Ogawa egg medium are transferred to fresh slants supplemented with sodium salicylate (0.5 mg/ml), which inhibits *Mycobacterium tuberculosis* (Tsukamura, 1962). Smears, prepared from colonies growing on supplemented slants after 3 weeks of incubation at 37°C, are stained by the Ziehl-Neelsen method and observed by light microscopy. Slightly acid-fast, rod-shaped bacteria are typical of gordoniae; those strongly acid-fast are mycobacteria. Gordoniae produce rough, reddish or pinkish colonies on Ogawa egg slants that have been plugged with cotton wool.

Large numbers of gordoniae and tsukamurellae have been isolated on glucose yeast extract agar plates (Gordon and Mihm, 1962) supplemented with cycloheximide and incubated at 30°C for 14 days following inoculation with serially diluted samples collected from foaming activated sludge plants (Goodfellow et al., 1996; Goodfellow et al., 1998). Gordoniae were recognized by their ability to produce rough, grayish-pink dry colonies and tsukamurellae by their characteristic deep orange, dry colonies. Prelim-

inary characterization studies showed that the former could be assigned to several novel centers of taxonomic variation within the genus *Gordonia*. Subsequent more exacting studies on representative tsukamurellae led to them being classified into two novel species, namely *T. spumae* and *T. pseudospumae* (Nam et al., 2003; Nam et al., 2004b).

The best media for the isolation of *G. amarae* strains are Czapek's agar supplemented with yeast extract (Higgins and Lechevalier, 1969) and glycerol agar (Gordon and Smith, 1953); these media yield visible colonies in 5–7 days at 38°C (Lechevalier and Lechevalier, 1974; Lechevalier et al., 1976). Similarly, *G. rubripertincta* strains have been isolated on Münz paraffin agar and Winogradsky's nitrate agar supplemented with paraffin (Nesterenko et al., 1978a). Novel gordoniae have been isolated from diverse environmental samples using selective enrichment protocols; organisms isolated in this way have been characterized as *G. alkanivorans* (Kummer et al., 1999), *G. amicalis* (Kim et al., 2000), *G. desulfuricans* (Kim et al., 1999), *G. nitida* (Yoon et al., 2000c), *G. paraffinivorans* (Xue et al., 2003), and *G. sihwensis* (Kim et al., 2003).

The first successful isolation of the relatively slow-growing *S. piniformis* from activated sludge foam and mixed liquor involved the application of a micromanipulatory technique (Blackall et al., 1989b). A Skerman micromanipulator (Skerman, 1968) was used to isolate acute-angled branching filaments from activated sludge samples taken from plants in Queensland, Australia; the filaments were transferred to either yeast glucose agar or tryptone yeast extract agar plates and incubated at a range of temperatures. Visible colonies (1–2 mm in diameter) of *S. piniformis* grew within 10–21 days. The organism has been micromanipulated from activated sludge foam samples taken from various plants in Australia. These findings suggest that the incidence of *S. piniformis* in activated sludge foams has been underreported, as the slow and variable growth of skermaniae means that they are likely to be outcompeted on isolation plates by faster growing mycolic acid-containing actinomycetes, such as *G. amarae* (Soddell and Seviour, 1990; Soddell and Seviour, 1994; Soddell et al., 1992). *Gordonia* and *Tsukamurella* strains, including *G. amarae*, have also been isolated from foaming activated sludge plants by micromanipulation (Tandoi et al., 1992; Seong et al., 1993; Stainsby et al., 2002).

A special semisolid medium, the main nutritive constituents of which were proteose peptone, rabbit serum, gelatin, mineral rabbit kidney, and carbohydrates, were used for the original isolation of *Tsukamurella paurometabola* (Steinhaus, 1941). The organism grew in 24–48 h when subsequently transferred to beef

infusion agar. *Tsukamurella strandjordii* and *T. tyrosinosolvens* were obtained directly from blood cultures (Yassin et al., 1997; Kattar et al., 2001), and *T. pulmonis* was obtained from sputum following decontamination with *n*-acetyl-L-cysteine, centrifugation, and cultivation on Lowenstein-Jensen medium (Yassin et al., 1997).

Gordoniae and tsukamurellae grow well on most standard laboratory media, including Bennett (Jones, 1949), brain heart infusion (Difco 0418), modified Sauton supplemented with thiamine (Mordarska et al., 1972), glucose yeast extract (Waksman, 1950) agars, Lowenstein-Jensen medium (BBL 20908), and skermaniae on yeast glucose and tryptone yeast extract agars (Blackall et al., 1989b).

The Family Nocardiaceae

CLASSICAL METHODS OF SELECTIVE ISOLATION FOR NOCARDIAE AND RHODOCOCCHI. Classical isolation procedures have depended on the capacity of nocardiae and rhodococci to use hydrocarbons as sole sources of carbon for energy and growth (Cross et al., 1976; Tárnok, 1976). Modifications of Söhngen's paraffin baiting method (Söhngen, 1913) have often been used to isolate *Nocardia* and *Rhodococcus* strains from soil (Portaels, 1976; Schaal and Bickenbach, 1978a) but are of little value in quantitative studies because they merely indicate the presence or absence of the organisms in samples. Many other bacteria and fungi that metabolize paraffin wax frequently outgrow nocardiae and rhodococci on coated glass rods and render isolation impossible. Alternative isolation methods, such as inoculating guinea pig or hamster testicles with soil suspensions supplemented with penicillin and streptomycin (Conti-Diaz et al., 1971) or plating suspensions onto media that contain sodium azide and cholesterol acetate (Farmer, 1962), underestimate populations of nocardiae and rhodococci in natural habitats.

SELECTIVE ISOLATION OF NOCARDIAE. Large numbers of nocardiae have been isolated from soil by plating out soil suspensions onto diagnostic sensitivity test (DST) agar supplemented with antifungal and various combinations of antibacterial antibiotics (Orchard and Goodfellow, 1974; Orchard et al., 1977; Maldonado et al., 2000). Inoculated plates are incubated for up to 21 days at 25°C. Colonies with pink to red stroma, covered to a greater or lesser extent with white aerial hyphae, are characteristic of nocardiae. To date, most isolates have been classified as *N. asteroides*, although laboratory strains of *N. brasiliensis* and *N. otitidiscaviarum* do grow on DST media (Orchard et al., 1977). At least some strains of *N. asteroides* will likely be inhibited by the antibacterial antibiotics in

DST agar (Schaal and Heimerzheim, 1974). A selective medium free of such antibiotics has been used to isolate *N. asteroides* from clinical material (Schaal, 1972).

Sabouraud dextrose agar supplemented with chloramphenicol has been recommended for the recovery of *Nocardia* species from sputum specimens (Ajello and Roberts, 1981), but many nocardiae are inhibited by chloramphenicol (Gutmann et al., 1983). There is encouraging evidence that chemically defined media containing paraffin agar may be useful for the selective isolation of nocardiae from clinical specimens (Shawar et al., 1990). Nonselective media such as brain heart infusion and Sabouraud dextrose agars have been recommended for the isolation of *Nocardia* species from clinical material (Schaal, 1977). Decontamination of respiratory specimens has been shown to be toxic for nocardiae (Murray et al., 1987). However, Hamid et al. (2001) isolated *N. africana* strains on Lowenstein-Jensen slopes that had been inoculated with sputum samples from patients with pulmonary diseases then treated with the digestion-decontamination procedure of Roberts et al. (1991); most of the patients either had not responded to treatment with anti-tubercular drugs or had responded and then relapsed.

Nocardia asteroides and *N. otitidiscaviarum* have been isolated by plating sewage foam onto either Czapek's agar supplemented with yeast extract (0.2%; Higgins and Lechevalier, 1969) or glycerol agar (Gordon and Smith, 1953) and incubating plates at 28°C for 5–7 days. Using nitrite medium (Winogradsky, 1949), Cross et al. (1976) reported high numbers of nocardiae from soils in the Union of Soviet Socialist Republics, but it seems likely that many of their isolates were rhodococci. However, nocardiae are common in soil and have been isolated serendipitously in small numbers on nutrient rich media, as exemplified by the growth of *N. beijingensis* on glucose asparagine agar (Wang et al., 2001), *N. caishijiensis* on Bennett agar (Zhang et al., 2003), *N. cerradoensis* on R5 agar (Albuquerque de Barros et al., 2003), *N. neocaledoniensis* on oatmeal agar (Saintpierre-Bonaccio et al., 2004), *N. tenerifensis* on soil extract agar (Kämpfer et al., 2004), and *N. xishanensis* on modified Sauton agar (Zhang et al., 2004).

Nocardiae grow well on most laboratory media, including brain heart infusion (Difco 0418), nutrient, Sabouraud dextrose, Bennett (Jones, 1949), yeast extract-glucose (Waksman, 1950), modified Sauton (Mordarska et al., 1972), and yeast-malt extract (ISP medium 2; Difco 0770) agars. Media should be incubated aerobically at 25–37°C for up to 3 weeks.

SELECTIVE ISOLATION OF RHODOCOCCHI. A heat-pretreatment method combined

with a selective medium has been devised to isolate *Rhodococcus coprophilus* from both aquatic and terrestrial habitats (Rowbotham and Cross, 1977a). Thus, environmental samples (2 ml) of cream, milk, or water in 100- × 12-mm glass tubes sealed with silicon rubber bungs are heated in a water bath for 6 min at 55°C prior to further dilution or plating out. Water samples are stored at 4°C before heating. Suspensions of dung, grass, soil (1:10), or hay (1:50) are homogenized in one-quarter-strength Ringer's solution containing gelatin (0.01%), pH 7.0, before heat pretreatment. Immediately after pretreatment, samples are shaken on a Vortex mixer and portions (0.2 ml) spread onto M3 agar plates (see Media for Isolation and Cultivation in this Chapter), which are incubated at 30°C for 7 days.

Rhodococcus luteus strains were isolated from soil and the skin and intestinal contents of carp on mineral salts agar enriched with *n*-alkanes and incubated at 28°C (Nesterenko et al., 1982); *R. marinonascens* were isolated from marine sediments using a number of rich nutrient media supplemented with seawater and incubated for 8–12 weeks at 18°C (Weyland, 1969), and *R. erythropolis* and *R. rhodochrous* were isolated from mineral salts media supplemented with *m*-cresol or phenol (Gray and Thornton, 1928). Similarly, *R. equi* was isolated from soil, feces, lymph nodes, and the intestinal contents of several animal species using a selective medium (NANAT medium) supplemented with cycloheximide, nalidixic acid, novobiocin, and potassium tellurite (Woolcock et al., 1979; Mutimer and Woolcock, 1980). A selective enrichment broth (TANT broth) containing cycloheximide, nalidixic acid, penicillin, and potassium tellurite incubated at 30°C and used in conjunction with Tinsdale medium (Oxoid) and modified M3 medium has also been used to isolate *R. equi* (Barton and Hughes, 1981).

Rhodococci have been isolated from soil using Czapek's agar (Higgins and Lechevalier, 1969), glycerol agar (Gordon and Smith, 1953), and Winogradsky's nitrate medium (Winogradsky, 1949) and from diseased sweet peas using potato dextrose agar (Tilford, 1936). Novel strains have been isolated from a range of environmental samples using selective enrichment procedures, as illustrated by *R. aetherivorans* (Goodfellow et al., 2004), *R. koreensis* (Yoon et al., 2000a), *R. percolatus* (Briglia et al., 1996), *R. pyridinivorans* (Yoon et al., 2000b) and *R. tukisamuensis* (Matsuyama et al., 2003).

Rhodococci grow well on standard laboratory media such as Bennett (Jones, 1949), brain heart infusion (Difco 0418), glucose yeast extract (Waksman, 1950), modified Sauton plus thiamine (Mordarska et al., 1972), and nutrient

agars and Lowenstein-Jensen medium (BBL 20908).

Media for Isolation and Cultivation

The following are the recipes for those media mentioned in the preceding section that are not commercially available.

Isolation Media

Alkaline Broth (Duckworth et al., 1998)

Glucose	10 g
Peptone (Difco)	0.5 g
Yeast extract (Difco)	0.5 g
K ₂ HPO ₄	0.1 g
MgSO ₄ · 7H ₂ O	0.2 g
NaCl	40 g
Na ₂ CO ₃	10 g
Deionized water	1 liter

Autoclave NaCl and Na₂CO₃ separately and add these to the organic components, including 1.5% (w/v) agar, for solid media.

AT Medium (Yumoto et al., 2002)

KNO ₃	5.0 g
KH ₂ PO ₄	0.5 g
MgSO ₄ · 7H ₂ O	0.5 g
FeSO ₄ · 7H ₂ O	0.01 g
CaCl ₂ · 2H ₂ O	0.02 g
MnSO ₄ · nH ₂ O	0.01 g
ZnSO ₄ · 7H ₂ O	0.0005 g
Agar	15 g
100 mM NaHCO ₃ /Na ₂ CO ₃	1 liter

Dissolve the buffer in deionized water and adjust to pH 10. Vaporize *n*-tetradecane, the sole carbon source, onto the surface of the agar plate by inverting the plate over a piece of filter paper that had been soaked in *n*-tetradecane.

Chitin Agar (Weyland, 1969)

Chitin, hydrolyzed and precipitated	10 g
Peptone	0.5 g
Yeast extract	0.1 g
FePO ₄ · H ₂ O	0.01 g
Seawater	750 ml
Distilled water	250 ml
Agar	15 g

Adjust to pH 7.5.

Czapek-Dox Agar (Weyland, 1969)

Sucrose	15 g
NaNO ₃	2 g
FePO ₄ · H ₂ O	0.01 g
Magnesium glycerophosphate	0.5 g
Seawater	750 ml
Distilled water	250 ml
Agar	15 g

Adjust to pH 7.6–7.8.

N-GB>DST Agar (Orchard and Goodfellow, 1974)

Supplement diagnostic sensitivity (DST) agar (Oxoid, CM261) with cycloheximide and nystatin (antifungal antibiotics) and various concentrations of chlortetracycline HCl, demethylchlortetracycline HCl, and methacycline HCl (antibacterial antibiotics). Autoclave the DST agar and cycloheximide separately at 15 psi (1.013×10^5 Pa) for 20 min, and filter the remaining antibiotics. Pipet the individual antibiotics separately into Petri dishes and add the basal medium to give the following concentrations (in $\mu\text{g/ml}$) for four different media:

Medium 1: demethylchlortetracycline HCl (demeclocycline HCl), 5; actidione, 50; and nystatin, 50.

Medium 2: methacycline HCl, 10; actidione, 50; and nystatin, 50.

Medium 3: chlortetracycline HCl (aureomycin), 45; demethylchlortetracycline HCl, 5; actidione, 50; and nystatin, 50.

Medium 4: chlortetracycline HCl, 45; methacycline HCl, 10; actidione, 50; and nystatin, 50.

Media 1 and 2 generally give higher counts of *Nocardia* because of the satisfactory inhibition of other soil bacteria. However, when large mixed populations of bacteria occur, the more selective formulations, media 3 and 4, may be required. The number of unwanted bacteria can also be reduced by heating soil suspensions (2 ml) in a water bath at 55°C for 6 min.

Glucose Extract Agar (Gordon and Mihm, 1962)

Glucose	10 g
Yeast extract	10 g
Agar	15 g
Distilled water	1 liter

Adjust to pH 7.2. Sterilize cycloheximide by membrane filtration and add to the autoclaved and cooled medium to give a final concentration of $50 \mu\text{l} \cdot \text{ml}^{-1}$.

Glycerol Agar (Gordon and Smith, 1953)

Beef extract	3 g
Glycerol	7%
Peptone	5 g
Agar	15 g
Soil extract	1 liter

Adjust to pH 7.0. Prepare soil extract by autoclaving 1000 g of air-dried soil (that has been sifted through a no. 9 mesh screen) with 2.4 liter of tap water at 121°C for 60 min. Decant the preparation and filter through paper pulp.

M3 Agar (Rowbotham and Cross, 1977a)

KH_2PO_4	0.466 g
Na_2HPO_4	0.732 g
KNO_3	0.01 g
NaCl	0.29 g
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.10 g
CaCO_3	0.02 g
$\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$	200 μg
$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$	180 μg
$\text{MnSO}_4 \cdot 7\text{H}_2\text{O}$	20 μg
Sodium propionate	0.20 g
Agar	18 g
Distilled water	1.0 liter

Adjust to pH 7.0. Filter cycloheximide and thiamine HCl by membrane filtration and add to the autoclaved and cooled medium to give final concentrations of 50 mg/liter and 4.0 mg/liter, respectively.

Mineral Salts Medium (Gray and Thornton, 1928)

K_2HPO_4	1.0 g
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.20 g
NaCl	0.10 g
$(\text{NH}_4)_2\text{SO}_4$ or KNO_3	0.5–1.0 g
CaCl_2	0.10 g
FeCl_3	0.02 g
Distilled water	1 liter

Inoculate soil (0.5–1 g) into 100 ml of mineral salts solution supplemented (after autoclaving) with m-cresol (0.05%) or phenol (0.05–1.0%). Subculture into fresh flasks containing the same medium, and plate isolates onto appropriate agar media containing m-cresol or phenol.

Mineral Salts Agar (Nesterenko et al., 1982)

KH_2PO_4	0.14 g
KNO_3	1.0 g
MgSO_4	0.1 g
NaCl	1.0 g
Na_2HPO_4	0.6 g
Mixture of <i>n</i> -alkanes (C-12 to C-22)	20.0 g
Distilled water	500 ml
Tap water	500 ml

Isolate rhodococci on this medium using the method of Yamada et al. (1963).

Mineral Salts Paraffin Agar (Shawar et al., 1990)

KH_2PO_4	3.0 g
K_2HPO_4	1.0 g
NH_4Cl	5.0 g
NH_4NO_3	1.0 g
FeSO_4	0.05 g
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.05 g
MnSO_4	0.05 g
ZnSO_4	0.05 g
Bacto agar (Difco)	17 g
Distilled water	1.0 liter

Adjust to pH 7.2. Prepare mineral salts paraffin agar by mixing 9 parts of the carbon-free agar medium with 1 part of paraffin oil (Soybolt viscosity at 37.8°C equals 345–355; J. T. Baker Chemical Co., Phillipsburg, NJ).

Modified Czapek's Agar (Higgins and Lechevalier, 1969)

NaNO_3	2.0 g
K_2HPO_4	1.0 g
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.5 g
KCl	0.5 g
FeSO_4	0.01 g
Sucrose	30.0 g
Yeast extract	2.0 g
Agar	15 g
Distilled water	1.0 liter

Adjust to pH 7.2.

Münz Paraffin Agar (Nesterenko et al., 1978a)

KH_2PO_4	0.14 g
KNO_3	1.0 g
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.10 g
NaCl	1.0 g
Na_2HPO_4	0.60 g
Agar	15 g
Distilled water	1.0 liter

Adjust to pH 7.2. Add 10 ml of liquid paraffin to the carbon-free medium after sterilization.

NANAT Medium (Woolcock et al., 1979)

Tryptone soya broth (Oxoid)	30 g
Yeast extract (Oxoid)	1 g
Agar (Difco)	15 g
Distilled water	1 liter

Sterilize at 121°C for 15 min. When cool add cycloheximide, 40 µg/ml; nalidixic acid, 20 µg/ml; and novobiocin, 25 µg/ml. Add potassium tellurite to 0.005%.

Nitrite Medium (Winogradsky, 1949)

NaNO ₂	2 g
Na ₂ CO ₄ (anhydrous)	1 g
K ₂ HPO ₄	0.5 g
Agar	15 g
Distilled water	1 liter

Ogawa Egg Medium (Tsukamura, 1972)

Whole chicken eggs	200 ml
Glycerol	6 ml
Malachite green (2%)	6 ml
Sodium glutamate (1%) plus KH ₂ PO ₄ (1%)	100 ml

Adjust to pH 6.8, and sterilize at 90°C for 60 min.

Tellurite-Actidione-Nalidixic Acid-Penicillin (TANT) Selective Enrichment Broth (Barton and Hughes, 1981)

Trypticase soy broth	30 g
Actidione (cycloheximide)	50 µg/ml
Nalidixic acid	20 µg/ml
Potassium tellurite	0.05 g
Penicillin	10 units/ml
Distilled water	1 liter

Inoculate TANT broth (10 ml) with a 1-g environmental sample (e.g., soil or feces) and incubate at 30°C for 6–7 days. Subculture the broth onto Tinsdale (Oxoid) agar supplemented with cycloheximide (50 µg/ml) and onto M3 agar (Rowbotham and Cross, 1977a) modified by the addition of 0.005% potassium tellurite. Colonies of *Rhodococcus equi* appear on these selective media after 4–5 days at 30°C.

Tryptone Yeast Extract Agar (Blackall et al., 1989b)

Glucose	5 g
Tryptone	3 g
Yeast extract	5 g
Distilled water	1 liter

Adjust to pH 7.0 and sterilize at 121°C for 15 min.

Yeast Glucose Agar (Blackall et al., 1989b)

Glucose	10 g
Yeast extract	10 g
Agar	15 g
Distilled water	1 liter

Adjust to pH 7.0 and sterilize at 121°C for 15 min.

Cultivation Media**Bennett Agar (Jones, 1949)**

Beef extract	1 g
Glucose	10 g
N-Z amine A (Enzymatic digest of casein)	2 g
Yeast extract	15 g

Adjust to pH 7.3 with NaOH. Alternatively, use modified Bennett agar; in it, glucose is replaced by glycerol (10 g) and N-Z amine A is replaced by Bactocastone (2 g, Difco).

Glucose-Yeast Extract Agar (Waksman, 1950)

Glucose	10 g
Yeast extract (50% solution)	20 ml

Adjust to pH 6.8.

Modified Sauton Medium (Mordarska et al., 1972)

Asparagine	5.0 g
Casein hydrolysate	2.0 g
Glucose	15.0 g
Sodium citrate	1.5 g
KH ₂ PO ₄	5.0 g
MgSO ₄ · 7H ₂ O	0.5 g
K ₂ SO ₄	0.5 g
Ferric ammonium citrate	Trace
Distilled water	1 liter

Adjust to pH 7.2. Sterilize the glucose separately. For the cultivation of *Rhodococcus* strains, supplement the medium with thiamine (50 mg/1 liter).

Preservation of Cultures

Serial transfer from agar slants of appropriate media (see above) every two months, with storage at 4°C between transfers, is the most convenient method for short-term storage. Lyophilization, storage in liquid nitrogen, or frozen glycerol suspensions can be used for long-term preservation. For lyophilization, cell masses are suspended in a suitable fluid, e.g., 7.5% (w/v) glucose serum or skimmed milk plus 7.5% (w/v) glucose. For storage in liquid nitrogen, the microorganisms are inoculated into small test tubes containing the appropriate medium and incubated until satisfactory growth is visible. The tubes are then closed with cotton wool plugs, dipped in liquid paraffin wax, and placed in a liquid nitrogen container.

Glycerol suspensions are prepared by scraping growth from heavily inoculated agar plates and making heavy suspensions in 3 ml of aqueous glycerol in small vials, which are then stored at –20°C (Wellington and Williams, 1978). The frozen glycerol suspensions serve both as a convenient means of long-term preservation and as a quick source of inoculum. Working inocula are obtained by thawing suspensions at room temperature prior to treating as for broth cultures. After use, glycerol suspensions are promptly frozen and stored again at –20°C.

Identification

Mycolic acid-containing bacteria can be difficult to distinguish from one another and from other actinomycetes using conventional staining and morphological properties. Thus, *Nocardia* strains that lack aerial hyphae cannot always be separated from mycobacteria, rhodococci or “bald” streptomycetes, whereas those producing abun-

dant aerial hyphae can be confused with members of the family Pseudonocardaceae. Reliable differentiation at the genus level depends to a large extent on the application of chemotaxonomic techniques. Simplified procedures are available for the detection of morphological and staining features (Goodfellow, 1996); cell wall constituents (Hancock, 1994), including the acyl type of muramic acid (Uchida et al., 1999); fatty acids, including mycolic acids (Minnikin et al., 1984b; Embley and Wait, 1994; Goodfellow, 1996); menaquinones (Collins et al., 1985b; Collins, 1994); and polar lipids (Suzuki et al., 1993). Such procedures will be progressively replaced by molecular systematic methods, including the use of nucleic acid probes, oligonucleotide primers and 16S rRNA gene sequencing (Stackebrandt et al., 1997; Laurent et al., 1999; Gürtler and Mayall, 2001a; Monciardini et al., 2002; Stach et al., 2003; Patel et al., 2004).

Identification at the Generic Level

Examination of whole-organism acid or alkaline methanolysates for the presence of mycolic acids is the first stage in the chemical procedure. Mycolic acids vary considerably in structure, ranging from relatively simple mixtures of saturated and unsaturated acids found in corynebacteria to highly complex mixtures characteristic of mycobacteria (Minnikin and Goodfellow, 1980a; Minnikin, 1993; Goodfellow and Magee, 1998a). Qualitative evaluation of mycolic acids can be easily and quickly achieved using a thin-layer chromatographic technique devised by Minnikin et al. (1975). Methanolysates of mycobacteria, other than *M. fallax* and *M. triviale* strains (Dobson et al., 1985), give a multispot pattern of mycolates, those of tsukamurellae give two spots, and those of dietziae, corynebacteria, gordoniae and rhodococci give a single spot, the R_f values of which reflect their chain length and structure (Goodfellow et al., 1976; Minnikin et al., 1980b; Hamid et al., 1993; Minnikin, 1993; Yassin et al., 1995; Yassin et al., 1996; Yassin et al., 1997). Mycolic esters can be positively identified on thin-layer chromatograms by their characteristic immobility when plates are subsequently washed in methanol-water (5:2, v/v; Minnikin et al., 1975). The patterns of mycolic acid types can be used for the identification of mycobacterial species (Goodfellow and Magee, 1998a; Minnikin et al., 1984a; Minnikin et al., 1984c; Minnikin et al., 1985b).

The mycolic acids from mycobacteria are precipitated from ether solution by addition of an equal (Kanetsuna and Bartoli, 1972) or double (Hecht and Causey, 1976) volume of ethanol. Mycolic acids from corynebacteria, gordoniae, nocardiae and rhodococci are not precipitated by

such a procedure, but Hecht and Causey (1976) detected their presence by thin-layer chromatography of the supernatant. A more reliable and sensitive precipitation procedure was introduced by Hamid et al. (1993) to separate mycobacteria from members of other mycolic acid-containing taxa. The basis of the method is the solubility of all mycolic acid methyl esters in acetonitrile/toluene (1:2, v/v) and the insolubility of those from mycobacteria in acetonitrile/toluene (3:2, v/v).

When the presence of mycolic acids has been detected, their esters can be isolated and studied further by pyrolysis gas chromatography, by mass spectrometry of the intact esters, by gas chromatography of trimethylsilyl ether derivatives, and by high-performance liquid chromatography (HPLC) of bromophenacyl derivatives. On pyrolysis, mycolic acid methyl esters yield long-chain methyl esters and aldehydes, which can be analyzed directly by use of gas pyrolysis, whereas the remaining mycolic acid-containing organisms produce esters with fewer carbon atoms (Table 1). Mycolic esters from *G. amarae* release unsaturated C₁₆ and C₁₈ major components (Lechevalier and Lechevalier, 1974) while production of unsaturated C₂₀ and C₂₂ esters characterizes the mycolates from *Tsukamurella paurometabola* (Goodfellow et al., 1978). Mycolic acids with unsaturation in the chain in the 2-position have been observed in two nocardial strains, *N. carnea* and *N. vaccinii*, but no details have been reported (Lechevalier and Lechevalier, 1974).

The pyrolysis of mycolates can be observed by mass spectrometry, where the highest peaks in the spectra correspond to anhydromycolates formed by loss of water from the parent molecule (Etémadi, 1967). The overall size of mycolates, their degree of unsaturation, and the nature of both long-alkyl chains may be determined by mass spectrometry. However, the complex mixtures of homologs usually present and the competing fragmentation pathways make interpretation difficult in some cases (Maurice et al., 1971; Alshamaony et al., 1976a; Alshamaony et al., 1976b). The analysis can be taken a stage further by using gas chromatography-mass spectrometry of trimethylsilyl and tertbutyldimethylsilyl derivatives of mycolic acids (Yano et al., 1978; Tomiyasu et al., 1981; Athalye et al., 1984; Pommier and Michel, 1985). This procedure separates mycolic ester derivatives into their homologous components, each of which can be analyzed by mass spectrometry. Capillary gas chromatography-mass spectrometry of trimethylsilyl ester derivatives of mycolic acid methyl esters has been used to distinguish among *Dietzia*, *Gordonia* and *Rhodococcus* strains (Nishiuchi et al., 2000) and to reveal differences in the mycolic acid profiles of *N. asteroides*, *N. farcinica*

and *N. nova*" strains (Butler et al., 1986; Butler et al., 1996; Butler et al., 1999; Baba et al., 1997; Nishiuchi et al., 1999; Butler and Guthertz, 2001).

Different classes of mycobacterial mycolic acids can be separated by HPLC (Qureshi et al., 1978; Steck et al., 1978; Ramos, 1994; Kaneda et al., 1995; Rhodes et al., 2003). This separation is based on the chain lengths, the degree of unsaturation, and other functional groups found in these fatty acids (Svensson et al., 1982). Reverse-phase HPLC of *p*-bromophenacyl esters of mycolic acids may provide a rapid way of distinguishing between mycolic acid-containing genera (Butler et al., 1986). A standardized method for HPLC identification of mycobacteria and an associated database are available (Butler et al., 1996).

Representatives of the genus *Rhodococcus* generally contain longer mycolic acids (34–52 carbon atoms) than those of *Corynebacterium* (22–38 carbon atoms), but an unambiguous distinction between members of the two genera cannot be made by analysis of mycolic acids alone (Collins et al., 1982b). Several rhodococci have mycolic acids that overlap in size with those of corynebacteria (e.g., *R. equi*; Collins et al., 1982b; Barton et al., 1989). Rhodococci are aerobic; although the vast majority of corynebacteria are undoubtedly facultative, obligate aerobic strains do occur which cannot be assigned with confidence to one genus or the other. Criteria that may prove to be of value in the identification of such "difficult strains" include information from DNA base composition and peptidoglycan analyses.

Members of the genus *Rhodococcus* generally have DNA with a higher G+C content (63–73 mol%) than that of *Corynebacterium* (51–63 mol%), and rhodococci contain *n*-glycolyl not acetyl residues in the glycan moiety of their peptidoglycan (Fig. 1). Similarly, the presence of 10-methyloctadecanoic (tuberculostearic) acid and phosphatidylethanolamine can help in the assignment of strains between the two genera. Members of the genus *Rhodococcus* contain tuberculostearic acid whereas corynebacteria, with the exception of *C. bovis*, lack this fatty acid (Lechevalier et al., 1977; Collins et al., 1982c). All other mycolic acid-containing actinomycetes, apart from *M. goodii*, contain substantial amounts of tuberculostearic acid (Tisdall et al., 1979; Minnikin et al., 1985a). With the exception of corynebacteria and dietziae, all mycolic acid-containing strains contain phosphatidylethanolamine, in addition to diphosphatidylglycerol and the characteristic phosphatidylinositol mannosides (Lechevalier et al., 1977; Lechevalier et al., 1981; Minnikin et al., 1977; Rainey et al., 1995a).

Gordoniae, nocardiae, rhodococci and tsukamurellae can be separated solely on the basis of

their predominant menaquinones (Fig. 1). The presence of fully unsaturated menaquinones with nine isoprene units (Goodfellow et al., 1978; Collins and Jones, 1982a) serves to distinguish tsukamurellae from all other mycolic acid-containing actinomycetes. Similarly, nocardiae and skermaniae are characterized by a pseudo-tetrahydrogenated menaquinone with eight isoprene units where the end of the multiprenyl side chain is cyclized (Howarth et al., 1986; Collins et al., 1987; Blackall et al., 1989b; Chun et al., 1997). Gordoniae and rhodococci can be distinguished from one another and from most related strains, as the former contain dihydrogenated menaquinones with nine isoprene units as the predominant isoprenologue and the latter contain the corresponding menaquinone with eight isoprene units (Collins et al., 1977; Collins et al., 1985b). Detailed analytical procedures for determining menaquinone composition have been described (Minnikin et al., 1984d; Kroppenstedt, 1985; Collins, 1985a; Collins et al., 1987). A small-scale integrated chemotaxonomic procedure is available for the detection of wall and lipid markers (O'Donnell et al., 1985).

Susceptibility to bleomycin (2.5 µg/ml), 5-fluorouracil (20 µg/ml), and mitomycin (10 µg/ml) and β-galactosidase activity may prove useful in the differentiation of mycolic acid-containing genera (Tsukamura, 1974b; Tsukamura, 1981a; Tsukamura, 1981b; Tsukamura, 1982a). There is also evidence that rhodococci are more resistant than mycobacteria are to prothionamide (Ridell, 1983) and that they can be distinguished from the latter on the basis of the acid-fast stain, arylsulfatase activity, capacity to use sucrose as a carbon source, and inability to metabolize trimethylamine as a simultaneous carbon and nitrogen source (Tsukamura, 1971a). To separate *Rhodococcus* from *Mycobacterium* and *Nocardia* strains (Ridell and Norlin, 1973) and from *Corynebacterium* (Ridell, 1977) is also possible using diagnostic precipitinogens.

Identification at the Subgeneric Level

Dietzia species can be distinguished from one another using a few phenotypic tests, notably by whether they reduce nitrate, produce H₂S, hydrolyze urea, or utilize citrate, glutamate, mannitol, L-proline or succinate (Yumoto et al., 2002). Similarly, phenotypic tests have been weighted to separate the type strains of the two *Williamsia* species (Stach et al., 2004). Thus, *D. maris* DSM 44693^T, unlike *D. muralis* DSM 44343^T, uses D(+) mannitol, D(+) trehalose and D(+) xylose as sole carbon sources for energy and growth but not adonitol, D(+) mannose or meso-inositol. *Gordonia* species (Table 2) and *Tsukamurella* species (Table 3) can be

Table 2. Phenotypic characteristics separating the type strains of *Gordonia* species.^a

distinguished using a combination of phenotypic tests.

Nocardia species can be difficult to identify owing to the lack of suitable phenotypic tests. Diagnostic tests recommended for the separation of established nocardial species (Gordon et al., 1978; Goodfellow and Lechevalier, 1989b; Boiron et al., 1993) can be useful but tend to give presumptive identifications. Partial identification of the major causal agents of human infections, notably those causing nocardiosis, can be achieved using a few simple biochemical, degradation and nutritional tests (Table 4) though the time taken from the acquisition of specimens to species identification can take several weeks. The same battery of diagnostic phenotypic tests can be used to distinguish between nocardial species isolated from environmental samples (Table 5). Supplementary tests based upon antibiotic sensitivity and enzyme activity have been recom-

mended for the separation of some *Nocardia* species (Boiron and Provost, 1990a; Boiron and Provost, 1990b; Boiron et al., 1993). An abbreviated battery of tests has been proposed for the identification of medically relevant *Nocardia* species (Kiska et al., 2002). Laboratory specialists need to be aware of the occasional occurrence of atypical strains of *N. asteroides* (Boiron et al., 1990).

Molecular fingerprinting and sequencing procedures provide a rapid, sensitive and effective way of identifying clinically significant nocardiae. The use of the polymerase chain reaction (PCR) coupled with restriction endonuclease analysis of PCR products has provoked some interest for the separation of *Nocardia* species (Lungu et al., 1994; Steingrube et al., 1995; Steingrube et al., 1997; Wilson et al., 1998; Conville et al., 2000), as has ribotyping (Exmelin et al., 1996; Laurent et al., 1996; Isik et al., 2002).

and PCR-randomly amplified polymorphic DNA fingerprinting (Isik and Goodfellow, 2002). Isik and his coworkers assigned 47 representatives of 13 validly described species and 4 putatively novel *Nocardia* species to 19 groups; species-specific patterns were recorded for representatives of *N. brasiliensis*, *N. crassostreae*, *N. farcinica*, *N. otitidiscaviarum* and *N. seriola*. Pulsed field gel electrophoresis was used to distinguish between *N. asteroides* strains implicated in a suspected outbreak of nocardiosis (Louie et al., 1997) and *N. farcinica* strains isolated from postoperative infections (Blümel et al., 1998). Partial 16S rRNA gene sequencing has been recommended for the identification of *Nocardia* species (Cloud et al., 2004), as has a digoxigenin-labeled cDNA probe (McNeil et al., 1997). DNA probes have been prepared for the identification of *N. asteroides* using genomic libraries generated for selected strains of *N. asteroides* (Brownell and Belcher, 1990).

Serological tests for the diagnosis of *Nocardia* infections have been developed, but most of them have not reached the desired sensitivity or specificity. Crossreactions of nocardial antigens from culture filtrates or whole-

organism extracts from sera from cases of tuberculosis and leprosy have been reported (Shainhaus et al., 1978; Blumer and Kaufman, 1979). Antigens in culture filtrates have been used to define a species-specific antigen for *N. otitidiscaviarum* (Pier and Fichtner, 1971). Tests have also been devised to detect cutaneous hypersensitivity and humoral antibodies for the diagnosis of nocardiosis in humans and animals (Boiron et al., 1993; Bojalil and Zamora, 1993). An enzyme-linked immunosorbent assay (ELISA technique) based on a 55-kDa protein specific to *Nocardia* allowed the detection of antibodies in patients with cutaneous or pulmonary nocardiosis (Angeles and Sugar, 1987; Sugar and Angeles, 1987). A conventional solid-phase ELISA, based on two immunodominant antigens, was used to confirm the diagnosis of *N. brasiliensis* infections in cases of human mycetoma (Salinas-Carmona et al., 1993). The value of the immunoblot technique has been demonstrated in the diagnosis of nocardiosis (Boiron and Provost, 1990c; Boiron and Stynen, 1992a). Monoclonal antibodies developed for use in the localization, purification and characterization of *Nocardia* antigens may serve as diagnostic reagents (Jimenez et

al., 1990), as may those raised against a specific 54-kDa protein (Boiron et al., 1992b).

Reliable typing methods are needed to determine the infectious source and mode of transmission of clinically significant nocardiae, particularly since hospital acquired nocardiosis seems to be an emerging problem (Schaal and Lee, 1992; McNeil and Brown, 1994). Antigens in culture filtrates have been used to establish four serotypes within *N. asteroides* and to determine cutaneous hypersensitivity in human patients and cattle infected with *N. asteroides*, *N. brasiliensis* and *N. otitidiscaviarum* (Pier et al., 1968; Salman et al., 1982). These antigens were used to good effect in epidemiological studies of group infections in humans (Stevens et al., 1981) and cattle (Pier and Fichtner, 1981). Comparisons of plasmid (Jonsson et al., 1986) and restriction fragment length polymorphism (RFLP) profiles (Paterson et al., 1992) have been used to type *N. asteroides* isolates. Strains assigned to the *N. asteroides* complex have been distinguished by ribotyping (Exmelin et al., 1996; Laurent et al., 1996). Pulsed-field gel electrophoresis was used to detect an endemic *N. farcinica* strain responsible for postoperative wound infections, possibly after aerogenic transmission (Blümel et al., 1998).

Members assigned to the four 16S rRNA rhodococcal subclades (Fig. 4) have unique nucleotide signatures (Goodfellow et al., 1998b). Criteria useful for differentiating between members of the *R. erythropolis* and *R. rhodochrous* subclades are shown in Tables 6 and 7, respectively. However, a better panel of phenotypic tests is needed to further improve the identification of rhodococcal species. Rapid enzyme tests show promise in this respect (Mutimer and Woolcock, 1982; Goodfellow et al., 1987; Goodfellow et al., 1990; Boiron et al., 1993; Klatte et al., 1994). PCR primers can be used to distinguish *R. equi* from members of other mycolic acid-containing actinomycetes (Bell et al., 1996). Several PCR-based rapid diagnostic tools are available for the diagnosis and control of pathogenic *R. equi* strains (Takai et al., 1998; Vivrette et al., 2000; Sellon et al., 2001; Arriaga et al., 2002; Ladrón et al., 2003). These methods are based on the IP1/IP2 primer pair designed by Takai et al. (1998) and specific for strains carrying the vap A+ genotype. A simple modification of this approach allows *R. equi* strains to be classified according to their *vap A-vap B* status (Oldfield et al., 2004). The whole-organism protein patterns may also be useful in the identification of *R. equi* (Chirino-Trejo and Prescott, 1987b).

Early detection of *R. equi* disease in foals may be achieved by B-cell epitope mapping of the VapA protein (Vanniasinkan et al., 2001). A comparison has been made of a number of meth-

ods used for the diagnosis of *R. equi* pneumonia in foals (Sellon et al., 2001). Ribotyping is a potentially useful epidemiological tool for unravelling relationships between *R. equi* isolates (Lasker et al., 1992); there is evidence that this taxon is heterogeneous (Goodfellow et al., 1982b; Butler et al., 1987; Gotoh et al., 1991; McMinn et al., 2000). PCR amplification of the *Fas-I* gene has been used to detect virulent strains of the plant pathogen *R. fascians* (Stange et al., 1996).

Comprehensive comparative taxonomic studies designed to highlight markers that can be weighted for diagnostic purposes are now possible given the improvements in the classification of *Gordonia*, *Rhodococcus* and *Tsukamurella* strains. Serological techniques may prove to be of value in distinguishing between species assigned to these genera (Hyman and Chaparas, 1977). Whole cell protein patterns may also be useful in the identification of *R. equi* (Chirino-Trejo and Prescott, 1987).

Pathogenicity

Nocardiae cause a wide range of infections in humans, the most serious of which are actinomycetoma and nocardiosis (Pulverer and Schaal, 1978; Schaal and Beaman, 1984; Schaal, 1997; Pujic and Beaman, 2001; Beaman, 2002). An understanding of the causal agents of these diseases is critical as lesions associated with infections lack distinctive clinical features and may not respond to antimicrobial drugs used to treat common suppurative and septicemic processes. The primary causal agents of actinomycetoma are *Actinomadura* species (see The Family Thermomonosporaceae in this Volume) and *N. asteroides*, *N. brasiliensis* and *S. somaliensis* (see The Family Streptomycetaceae, Part I: Taxonomy in this Volume and The Family Streptomycetaceae, Part II: Molecular Biology in this Volume). Other nocardial species associated with the disease include *N. farcinica* (Schaal and Lee, 1992), *N. otitidiscaviarum* (Alteras and Feuerman, 1986; Saarinen et al., 2001), *N. pseudobrasiliensis* (Rainey et al., 1996) and *N. transvalensis* (Mirza and Campbell, 1994; Poonwan et al., 1995). Incidence figures for actinomycetoma need to be interpreted with care as the disease is not notifiable and the causal agents can be difficult to identify. Immunologically based diagnostic methods have been used to detect specific antibodies induced by the causal agents, though immunological crossreactions with other pathogenic agents can occur (De Magaldi and Mackenzie, 1990; Salinas-Carmona et al., 1993; Salinas-Carmona, 2001).

Data from Goodfellow et al. (2004) and Jones et al. (2004).

The clinical picture of actinomycetoma is relatively uniform irrespective of the causal agent. The disease is characterized by abscesses and subcutaneous granulomata and by areas of induration. Sinus tracts, often multiple, may discharge granules that have a characteristic size, shape and color. The granules consist of small colonies of the infective agent surrounded by masses of inflammatory cells. Infections are frequently through the foot, especially in localities where people cannot afford footwear. However, many extrapedal cases are seen involving parts of the body that come into contact with soil. The disease process usually starts at the site of a localized injury such as a puncture wound caused by thorns or splinters. The disease is mainly restricted to tropical and subtropical regions, though mycetomas are occasionally seen in patients from temperate countries. Human mycetoma has been simulated in a mouse model (González-Ochoa, 1973), which has been used to study some aspects of host-parasite relationships (Ortiz-Ortiz et al., 1984).

Nocardiosis usually develops as an opportunistic infection complicating debilitating primary diseases such as diabetes, leukemia, lymphoma and other neoplasms or in patients undergoing immunosuppressive therapeutic procedures (Schaal and Beaman, 1984; McNeil and Brown,

1994; Schaal, 1997; Beaman, 2000a; Beaman, 2002). Accurate diagnosis of the disease depends on the isolation and identification of the causal agent from clinical material, as clinical, radiological and histopathological findings are insufficient for this purpose. Isolation and identification procedures are not straightforward; hence, the true incidence of nocardiosis is masked, a problem which is exacerbated by poor documentation.

Recent increases in the reported frequency of human nocardial infections can be attributed to better clinical microbiological awareness, improved selective isolation and identification procedures, and the extensive use of suppressive drugs; there is also an increasing realization that pulmonary nocardiosis can be misdiagnosed as tuberculosis (Idigbe et al., 1992; Hamid et al., 2001). In France, up to 250 cases of nocardiosis have been estimated annually (Boiron et al., 1990), and corresponding figures from the United States suggest over 1000 cases of the disease per year (Beaman, 1988). Localized cutaneous, subcutaneous and lymphocutaneous nocardioses occur in healthy individuals (Lemar, 1996; Gaude et al., 1999).

Nocardiosis is usually considered to be a late-presenting, community acquired infection though it is becoming increasingly evident that

the disease is transmissible. Clusters of patients with *N. asteroides* infections have been reported from heart (Krick et al., 1975; Simpson et al., 1981), liver (Sahathevan et al., 1991) and renal transplant units (Huang et al., 1980; Baddour et al., 1986). Similarly, a cluster of *N. farcinica* post-operative wound infections in patients undergoing cardiac and other vascular surgeries was attributed to environmental factors (Schaal, 1991). Nocardial infections occur in AIDS patients (Kim et al., 1991; Uttamchandani et al., 1994); the suggestion by some clinicians that nocardiosis is a rare complication in AIDS patients has been challenged (Beaman and Beaman, 1994).

The mechanism of pathogenesis and host immunity to nocardial infection has been promoted by Blaine Beaman and his colleagues using murine models (Beaman et al., 1980a; Beaman et al., 1980b; Beaman and Beaman, 1994; Beaman and Beaman, 2000b). Virulent strains of *N. asteroides* are facultative intracellular pathogens that can be grown in a range of cells from humans and experimental animals (Beaman, 1984). The mechanisms of pathogenicity are multiple, complex and not fully understood (Beaman et al., 1992). The virulence of *N. asteroides* strains appears to be influenced by factors that include the age of the culture, its rate of growth, the route of infection, and its capacity to inhibit phagosome-lysosome fusion, resist oxidative killing mechanisms of phagocytes, and alter lysosomal enzymes within phagocytes. The mechanisms of host resistance to nocardiae are complex and poorly understood (Beaman, 1992). L-Forms have been isolated from humans, but their role in human disease is not known (Beaman, 1982).

In systemic nocardiosis, the primary lesion is usually the lungs, but secondary and often fatal infections may develop in the central nervous system and less frequently in other internal organs. Nocardiae appear to invade the host by direct inhalation of contaminated dust particles or through soil contaminated wounds. Localized cutaneous or subcutaneous infections are usually of a primary nature and are mainly caused by *N. asteroides* or *N. brasiliensis*.

Until recently, dietziae, gordoniae, rhodococci and tsukamurellae were rarely encountered as agents of human infections but are now seen as emerging pathogens. Clinicians need to be aware of the pathogenic potential of these organisms, especially when treating AIDS patients and similarly immunocompromised individuals. *Rhodococcus equi* is known to be an important human pulmonary pathogen of immunocompromised patients, where it causes cavitary pneumonia (Van Etta et al., 1983; Eberzole and Paturzo, 1988; Drancourt et al., 1992; McNeil and Brown, 1994; Scott et al., 1995; Mosser and Hondalus,

1996). A small number of cases in immunocompetent hosts has been reported (Kedlaya et al., 2001).

Rhodococcus equi is pathogenic for foals (Barton and Hughes, 1980; Prescott, 1991). Indeed, the organism was first isolated from the lungs of a foal with chronic suppurating bronchopneumonia (Magnusson, 1923). Pneumonia caused by *R. equi* strains commonly affects foals the ages of 1–6 months with high mortality and has been estimated to account for about 3% of the total number of foal deaths per year (Prescott, 1991). In Ontario it was reported to cause 10% of deaths of foals under 6 months old (Zink et al., 1986). The route of infection is thought to be by inhalation or ingestion through grazing on infected land (Martens et al., 1982; Johnson et al., 1983a; Johnson et al., 1983b).

In the animal host, *R. equi* strains are taken up in macrophages. Equine *R. equi* virulence has a high positive correlation with the expression of the *vapA* gene (Tkachuk-Saad and Prescott, 1991; Haites et al., 1997; Morton et al., 2001), which is located on a circular plasmid, the virulence associated plasmid (VAP; Takai et al., 2000). The *vap* operon of the equine isolate ATCC 33701 is borne within a 27,000-bp “pathogenicity island” and encodes at least four functional genes, *vapA*, *vapC*, *vapD*, *vapE* and *vapF*. Immunoblotting studies (Byrne et al., 2001) show that the gene products, VapA, a cell-surface lipoprotein, and VapC, VapD and VapE, all secreted proteins, are expressed during growth at 37°C but not at 30°C, a result in line with their putative role in virulence. A variant of *vapA*, known as *vapB* (Takai et al., 2000; Byrne et al., 2001), has been identified in some equine isolates from pigs (Takai et al., 1996) and humans (Takai et al., 1994; Takai et al., 1995). A PCR technique allows the selective isolation of *vapA* and *vapB* (Oldfield et al., 2004); these workers showed that the high frequency of *vapA*⁺ amongst equine isolates was significant, thereby confirming the status of *vapA* as a reliable marker of equine virulence.

Oral immunization can protect foals against severe challenge with *R. equi* (Chirino-Trejo et al., 1987a). However, the humoral response to *R. equi* whole-cell antigens does not seem to be important in protection against disease (Chirino-Trejo and Prescott, 1987a). This observation is consistent with the behavior of the organism as a facultative intracellular pathogen (Zink et al., 1985).

Metabolism and Genetics

Early work on the genetics and metabolism of Nocardiaceae strains is difficult to interpret given

the uncertain taxonomic status of the tested organisms. Many investigations reported on “nocardiae” can be attributed to strains now classified in the genera *Gordonia* and *Rhodococcus* (Bradley, 1978a; Brownell and Denniston, 1984; Peczyńska-Czoch and Mordarski, 1988) or in the family Pseudonocardiaceae (Schupp et al., 1975; Matsushima et al., 1987; Hütter and Eckhardt, 1988). Larkin et al. (1998) have pointed out that many strains assigned to the genus *Rhodococcus* without the aid of 16S rRNA sequence data may belong to other genera, as exemplified by the transfer of *Rhodococcus chlorophenolicus* Apajalahti et al. 1986 to the genus *Mycobacterium* as *Mycobacterium chlorophenolicum* (Apajalahti et al., 1986) Häggblum et al. 1994. Conversely the polychlorinated biphenyl-degrading *Acinetobacter* strain sp. M5 was reclassified as *Rhodococcus globerulus* primarily on the basis of 16S rRNA gene sequence data (Asturias and Timmis, 1993; Asturias et al., 1994).

Clearly, rhodococci and related mycolic acid-containing organisms, notably gordoniae and tsukamurellae, are chemoorganotrophs characteristically exhibiting a remarkable degree of metabolic diversity that allows them to use an immense range of organic compounds as sources of carbon, nitrogen and micronutrients (Tárnok, 1976; Peczyńska-Czoch and Mordarski, 1988; Finnerty, 1992; Warhurst and Fewson, 1994; Arenskötter et al., 2004). The list of pathways covered in the review by Warhurst and Fewson (1994), while impressive, probably represents only a fraction of the true extent of the metabolic diversity within this group.

The catabolic potential of gordoniae, nocardiae, rhodococci and tsukamurellae, and probably dietziae and skermaniae, not only includes the capacity to assimilate carbohydrates and proteins but also unusual compounds, such as aliphatic hydrocarbons, aniline, bicyclic and polycyclic hydrocarbons, nitroaromatic compounds, pyridine, and sterols (Tárnok, 1976; Cain, 1981; Janke et al., 1986; Van Ginkel et al., 1987; Peczyńska-Czoch and Mordarski, 1988; Williams et al., 1989). Detergents and pesticides, including warfarin, are also modified (Goodfellow and Williams, 1983), and 1,2-epoxyalkanes are produced from 7-alkanes (Fukuhashi et al., 1981). The ability to synthesize complex lipids (Minnikin, 1982; Ionedá, 1988), including mycolic acids, distinguishes dietziae, gordoniae, nocardiae, rhodococci, skermaniae and tsukamurellae from all other bacteria apart from corynebacteria and mycobacteria. Phenol degradation by rhodococci has been examined in batch and continuous culture (Hensel and Straube, 1990; Straube et al., 1990), and oligocarboxiphily was reported for a rhodococcal strain labeled “*Nocardia corallina*” (Tárnok, 1976).

Rhodococci have frequently been isolated from soils polluted with petroleum (Nesterenko et al., 1978a; Nesterenko et al., 1978b) and have been implicated in the degradation of humic acid (Cross et al., 1976) and lignin-related compounds (Eggeling and Sahm, 1980; Eggeling and Sahm, 1981; Rast et al., 1980) and pesticides (Nagy et al., 1995). Their metabolic versatility includes the ability to break down acrylamide (Arai et al., 1980), aromatic hydrocarbons (Raymond et al., 1971), haloalkanes (Kesseler et al., 1996), and sulfonated azo dyes (Heiss et al., 1992).

Two main types of enzyme are involved in nitrile biotransformations by rhodococci; nitrilases catalyze the direct cleavage of nitriles to yield the corresponding acids and ammonia, whereas nitrile hydratases catalyze the hydration of nitriles to amides (Harper, 1977; Harper, 1985; Nagasawa et al., 1988a; Bunch, 1998). Nagasawa and his colleagues demonstrated the occurrence of a cobalt-induced and cobalt-containing nitrile hydratase in *Rhodococcus rhodochrous* J1; the cells of this organism also produce a nitrilase (Nagasawa et al., 1988b) that has been purified and characterized (Kobayashi et al., 1989a). A novel nitrilase that preferentially catalyzes the hydrolysis of aliphatic nitriles was detected in *R. rhodochrous* K22, a facultative crotononitrile-utilizing actinomycete (Kobayashi et al., 1990); this enzyme is remarkable in its broad substrate specificity for aliphatic nitriles. DNA probes for the α - and β -subunits of the *Rhodococcus* N 774 nitrile hydratase have been used to locate the region on the chromosome that codes for the nitrile hydratase gene (Ikehata et al., 1989). The nucleotide sequence of the nitrile hydratase gene of *R. rhodochrous* J1 has been determined (Kobayashi et al., 1990).

Gordonia strains are a potentially rich source of metabolic diversity. Members of this taxon have the capacity to degrade toxic environment-contaminating compounds, as exemplified by the isolation of strains with hydrocarbon-oxidizing, nitrile-metabolizing, rubber-degrading, and 3-ethylpyridine-degrading pathways (Brandão et al., 2001; Brandão et al., 2003) and novel desulfurizing enzymes (Gilbert et al., 1998; Rhee et al., 1998; Finkel'shtein et al., 1999; Kim et al., 1999).

Early developments in rhodococcal genetics were the subject of several comprehensive reviews (Adams and Brownell, 1976; Brownell and Denniston, 1984; Finnerty, 1992). Recombination was reported in the model organism *R. erythropolis* by Adams and Bradley (1963). Over 60 genetic traits were used in the development of a *R. erythropolis* linkage map, and temperate phages were made available as cloning vectors for establishing a gene cloning system. Genetic recombination was demonstrated between

rhodococcal strains labeled "*Nocardia opaca*" and "*Nocardia restricta*." A transferable plasmid described for a strain of the former carries traits allowing for chemolithoautotrophic growth (aut+), including genes for hydrogenase, phosphoribulokinase, and ribulose-bisphosphate-carboxylase production (Reh, 1981a; Reh and Schlegel, 1981b). The "*N. opaca*" strain is able to transfer the aut+ trait to related organisms and to *R. erythropolis*; in the presence of CO₂ and H₂O, it has a generation time of 7 h.

A miniplasmid has been characterized for a rhodococcal strain labeled "*R. corallina*" (Kirby and Usdin, 1985) and *Rhodococcus* genes encoding pigment production were cloned and expressed in *Escherichia coli* (Hill et al., 1989). Plasmid-determined transformation of *cis*-abienol and schareol has been achieved in "*Nocardia restricta*" JTS-162 (Hieda et al., 1982). A generalized transducing bacteriophage is available for *Rhodococcus erythropolis* (Dabbs, 1987).

The need for better genetic tools to characterize and exploit the diverse metabolic activities of members of the families Dietziaceae, Gordoniaceae, Nocardiaceae and Tsukamurellaceae is becoming increasingly evident. Much of the recent work has been focused on rhodococci as illustrated in two excellent reviews (Larkin et al., 1998; Kulakov and Larkin, 2002). These workers note that while considerable progress is being made in rhodococcal genetics, developments have been impeded by difficulties of choosing a model organism, extracting nucleic acids because of the recalcitrance of the rhodococcal cell wall, and the pleomorphic nature of many strains. Apparently, rhodococci exhibit considerable genomic instability.

Rhodococci contain plasmids that range from small cryptic closed circular molecules to large linear plasmids. Linear plasmids have been discovered in many strains and shown to code for a variety of functions such as biphenyl metabolism in *R. erythropolis* strain TA421 (Kosono et al., 1977), hydrogen autotrophy in *R. opacus* strain MR22 (Grzeszik et al., 1997), isopropylbenzene metabolism in *R. erythropolis* strain BD2 (Dabrock et al., 1994), and plant virulence and fasciation genes in *R. fascians* strain D188 (Crespi et al., 1992; Crespi et al., 1994). However, Pisabarro et al. (1998) did not detect any linear replicons in the megabase range in an analysis of several virulent and avirulent strains of *R. fascians*, a difference that may be related to the instability of the rhodococcal genome. Well-characterized circular plasmids are associated with pathogenicity determinants of *R. equi* (Takai et al., 1991; Takai et al., 1993; Takai et al., 1995) and the degradation of organic pollutants (Dabbs, 1998). Circular plasmids have been shown to code for diphenyl metabolism (Masai et al., 1997), chlo-

roalkane degradation (Kulakova et al., 1997), dibenzothiophene desulfurization (Denome et al., 1994; Denise-Larose et al., 1997), and 2-methylaniline metabolism (Schreiner et al., 1991). However, little is known about the replication, stable maintenance, and transfer of rhodococcal plasmids.

Broad-host-range plasmids that can replicate in different actinomycetes, including rhodococci, have yet to be identified (Larkin et al., 1998). This lack of suitable cloning vectors has encouraged several groups to search for DNA fragments of indigenous rhodococcal plasmids, which confer the ability to replicate in particular *Rhodococcus* strains when integrated into *Escherichia coli* replicons. Singer and Finnerty (1988), for instance, constructed the shuttle vector pMVS 301 (10.1 kb) from a 3.8-kb fragment of the cryptic 13.4-kb plasmid pMVS 300 from *Rhodococcus* strain H13-A. Additional cloning vectors have been constructed for different purposes as exemplified by shuttle vectors pK 4 and pRR-6, which have been used to study nitrile conversion by *R. rhodochrous* (Komeda et al., 1996a; Komeda et al., 1996b; Komeda et al., 1997) and to characterize dibenzothiophene desulfurization genes in *R. erythropolis* (Piddington et al., 1995; Li et al., 1996), respectively.

Gene expression and control in *Rhodococcus* are well covered in the review by Larkin et al. (1998). Many rhodococcal genes have been cloned and analyzed with an emphasis directed towards pathways involved in the degradation of aromatic compounds. Sequences are available for operon-like structures that encode the genes for the degradation of biphenyl (Masai et al., 1995), dibenzothiophene desulfurization (Denome et al., 1994), 3-hydroxyphenylpropionic acid (Barnes et al., 1997), isopropylbenzene (Kessler et al., 1996), and plant virulence loci (Crespi et al., 1994). Enzyme expression in rhodococci is dependent on specific inducers (Komeda et al., 1996a; Komeda et al., 1996b; Barnes et al., 1997; Labbé et al., 1997) or repressors (Li et al., 1996). Transcriptional regulation of the *R. rhodochrous* J1 nitrilase gene (*nitA*) has been analyzed in detail (Komeda et al., 1996b). The transcription of the *nitA* gene was inducible by isovaleronitrile, and a regulatory gene encoding the positive transcriptional regulator *nitR* was essential for the isovaleronitrile dependent induction. In contrast, the dibenzothiophene desulfurization (*dsz*) gene cluster is not inducible but is strongly repressed by sulfate- and sulfur-containing amino acids (Li et al., 1996).

The recent advances in rhodococcal genetics, while welcome, leave plenty of scope for further development. In particular, better cloning methods are needed, as are detailed functional analy-

ses of sequences of regulatory regions, inducers, and associated regulatory processes. Rapid advances can be anticipated on such fronts given the imminent availability of several rhodococcal whole genome sequences.

Genetic recombination and plasmids have been reported in *N. asteroides* (Kasweck et al., 1981; Kasweck and Little, 1982a; Kasweck et al., 1982b) and nocardiphages have been reported for *N. asteroides* (Pulverer et al., 1975; Prauser, 1976; Prauser, 1981b; Andrzejewski et al., 1978), *N. brasiliensis* (Pulverer et al., 1975), *N. carnea* (Williams et al., 1980), *N. otitidiscaviarum*, and *N. vaccinii* (Prauser, 1976). Members of the family Nocardiaceae are generally susceptible to nocardiphages but not strains classified in the families Mycobacteriaceae and Pseudonocardiaceae (Williams et al., 1980; Prauser, 1981a). Conversely, phages that lyse *Amycolatopsis mediterranei* are inactive against nocardiae (Thiemann et al., 1964).

Applications

Nitrile-converting biocatalysts are of industrial interest from the perspectives of treating toxic nitrile- and cyanide-containing wastes (Knowles and Wyatt, 1992) and as agents for the synthesis of chemicals (Liese et al., 2000). Rhodococcal nitrile-converting enzymes are being used commercially as catalysts to convert nitriles to corresponding higher value acids and amides, notably acrylic acid and acrylamide (Beard and Page, 1998; Hughes et al., 1998). These compounds are manufactured by chemical processes in vast amounts and are used to produce polymers for use as dispersants, flocculants and superabsorbents. The chemical production of acrylamide involves the use of a copper catalyst and a process that needs to be carried out at high temperature under pressure in a nitrogen atmosphere. In contrast, the nitrile hydratase-catalyzed process developed by the Nitto Chemical Industry Company in collaboration with Kyoto University for the production of acrylamide is performed at low temperature under atmospheric pressure using *Rhodococcus* strain N-774 as the biocatalyst. The establishment of an enzymic route to produce acrylamide was the first successful commercial biocatalyst process involving the production of a commodity chemical. The important features of the biocatalysts used by Nitto for acrylamide production have been described by Kobayashi et al. (1992).

Improved biocatalysts for acrylamide production were sought through the Kyoto/Nitto collaboration, a process that led to *Rhodococcus* strain J1 becoming a third-generation biocatalyst for the commercial production of acrylamide from

acrylonitrile. The nitrile hydratase of this organism, which is induced when the culture medium is supplemented with cobalt and crotonamide, has been shown to be a versatile and robust enzyme (Nagasawa and Yamada, 1990; Kobayashi et al., 1992; Yamada and Kobayashi, 1996). Given the widespread distribution of rhodococci in the environment, additional representatives of this taxon with similar or better enzymic properties seem likely to be discovered.

Mycolic acid-containing actinomycetes, notably rhodococci, may prove to be a valuable source of novel, commercially significant biosurfactants (Wagner et al., 1976; Gerson and Zajic, 1977; Blackall and Marshall, 1989a; Lang and Philp, 1998; Choi et al., 1999). Rhodococci respond to the presence of alkanes by producing biosurfactants that help them to use hydrophobic compounds as growth substrates (McDonald et al., 1981; Wagner et al., 1983; Kurane et al., 1995). Most attention has been focused on trehalose mycolates, notably those from *R. erythropolis* (Kretschmer et al., 1982; Uchida et al., 1989; Lang and Philp, 1998). Surfactants represent very large-scale production chemicals, the demand for which can be expected to increase (Desai and Banat, 1997).

The commercial interest in biosurfactants against chemically synthesized components is due to the increasing environmental concern associated with the continued use of the latter. Rhodococcal surface-active lipids are seen to have some favorable characteristics for certain applications, notably their lipophilicity, non-ionic nature, biodegradability, and low toxicity. These compounds can reduce the surface tension of aqueous solutions and the interfacial tension between aqueous and oil phases to levels observed with synthetic surfactants. Their commercial utilization is likely to be where high levels of purity are not required and in the growing environmental remediation industries.

Gordoniae and rhodococci are widespread in the environment through their ability to metabolize a wide range of organic pollutants, many of which are toxic (Dabbs, 1998; Brandão et al., 2001). They are able to survive in polluted habitats under near-starvation conditions (Warhurst and Fewson, 1994; Acharya and Desai, 1997) and have the capacity to degrade diverse hydrocarbons, including halogenated and long chain, as well as numerous substituted aromatic compounds (Tárnok, 1976; Peczynska-Czoch and Mordarski, 1988; Warhurst and Fewson, 1994). The ability of gordoniae and rhodococci to grow in highly polluted environments makes them attractive candidates for the selective removal of unwanted contaminants from commodity products and in bioremediation.

Desulfurization reactions have received a lot of attention because of their potential role in industrial-scale bipurification of coal and crude oil and its distillates by selective removal of contaminating organosulfur. Desulfurization pathways are of prime importance in the development of microbial fuel desulfurization technologies, as a cheap and environmentally friendly alternative to chemical processes. Desulfurizing enzymes remove the sulfur moiety from the organosulfur, leaving the carbon skeleton intact. Two types of desulfurization reaction are recognized. The dibenzothiophene (DBT) specific pathway desulfurizes DBT to inorganic sulfate and 2-hydroxybiphenyl, and the benzothiophene (BTH)-specific pathway desulfurizes BTH to 2- (2'-hydroxyphenyl) ethan-1-ol and probably inorganic sulfate. Considerable interest has been shown in the desulfurizing enzymes produced by *Gordonia* and *Rhodococcus* strains (Oldfield et al., 1998). The DBT-desulfurization pathway was originally identified in *R. erythropolis* strain IGTS8 and the BTH-desulfurization pathway in *Gordonia desulfuricans* strain 213E. Strains of *G. desulfuricans* may find particular application in the desulfurization of diesel fuel, which contains a high proportion of benzothiophene (McFarland et al., 1998).

Most clinically relevant microbial compounds have been natural products or derived from natural products. Among bacteria, actinomycetes have been found to have a unique capacity to produce novel bioactive compounds, notably antibiotics. Early pharmacological screening programs were focused on streptomycetes, but in recent times, the emphasis has switched to other actinomycete genera (Okani and Hotta, 1988; Lazzarini et al., 2000). This change represents a new and important dimension to secondary metabolite discovery, not least because it provides a quantum leap in the number and variety of genetic resources available for exploitation. Mycolic acid-containing actinomycetes have not featured prominently in search and discovery programs, but evidence shows that they may well be worth screening, as exemplified by the ability of the type strain of *Nocardia vinacea* to produce tubelactomicin A, a new 16-membered lactose antibiotic (Kinoshita et al., 2001).
